Figure 3 A schematic representation of the lectin complement pathway. The lectin pathway is activated when either MBL, collectin-11 or ficolins (structure for globular head of M-ficolin shown (PDB identifier: 2JHH)) bind to pathogen-specific carbohydrate arrays. This activates MASP-1 and MASP-2, converting them from zymogen (structures shown for MASP-1 (4IGD) and MASP-2 (1ZJK)) into active forms (structures shown for MASP-1 (3GOV) and MASP-2 (1Q3X)). Zymogen MASP-3 (4KKD) is also included. Activated MASP-2 binds and then cleaves C4 (structure for MASP-2/C4 shown: 4FXG) and C2, which combine to form the C3 convertase (C4bC2a) from whence the pathway culminates in cell lysis, opsonisation, and the release of chemotactic peptides.

MASP-1 was the first protease of the system identified (Ji *et al.*, 1993) and was thought to play a lone hand in activating the system until the discovery of MASP-2. Both molecules are capable of autoactivating and, following the discovery that MASP-2 was capable of cleaving both C4 and C2 (Vorup-Jensen *et al.*, 2000), while MASP-1 was inefficient at cleaving C4 in particular (Rossi *et al.*, 2001), it was thought for some time that MASP-2 was the sole activator of the lectin pathway. More recently, it has been shown that MASP-1 is necessary for efficient activation of MASP-2 and additionally contributes to the activation of the pathway further by playing a part in activating a fraction of the C2 activated by this pathway (Heja *et al.*, 2012). It is therefore clear, however, that MASP-2 is solely responsible for cleaving C4 and this becomes the pivotal reaction in pathway activation once MASP-2 has been activated. Initial studies showed that the CCP domains of MASP-2 play an important role in the efficient interaction between the protease and C4 (Rossi *et al.*, 2001; Ambrus *et al.*, 2003), while

the structure of the MASP-2/C4 complex has shown that both the CCP domains and the SP domains harbor exosites for C4 (Kidmose *et al.*, 2012). The precise details of how MASP-2 and MASP-1 cleave C2 efficiently have been less studied, aside from noting that the SP domain of MASP-2 appears to contain all of the required determinants to cleave C2 efficiently (Rossi *et al.*, 2001; Ambrus *et al.*, 2003).

When MASP-3 was first identified, initial experiments suggested that the enzyme played a role in regulating the complement system since it had low proteolytic activity, but could compete for binding sites on the lectin recognition molecules with MASP-1 and MASP-2 (Dahl *et al.*, 2001). Later, it was shown that murine MASP-3 was able to activate mouse factors D and B and thus activates the alternative pathway of complement in mice (Iwaki *et al.*, 2011). The relevance of this in the human system is, however, uncertain since similar results were not demonstrated in samples derived from human patients (Degn *et al.*, 2012). The role of MASP-3 in

complement is therefore unknown at this point, yet it is found in all vertebrates, including birds, which do not have MASP-1, for example, thus it is likely to have an important role. Most recently, it has been shown that mutants of MASP-3 are associated with the 3MC syndrome, characterized by skeletal and cranial deformities (Sirmaci *et al.*, 2010; Rooryck *et al.*, 2011). It is interesting to note here that mutants of the recognition molecule, CL-11, are also associated with this disease, suggesting that perhaps complexes of MASP-3 with CL-11 may play an important role in development. Genetic studies indicated that MASP-3 might be playing a role in neural crest migration in development of zebrafish embryos, suggesting a role for the enzyme in development (Rooryck *et al.*, 2011). Most mutants of the enzyme could clearly be predicted to be inactive, but our recent study (Yongqing *et al.*, 2013) has shown that two point mutants with uncertain outcomes with regard to the activity of the enzyme are indeed inactive and the solution of the first structure of MASP-3 (in a zymogen form) showed the mechanism whereby such a mutation causes the enzyme to be inactive. Following on directly from this, the structure of the active form of the enzyme in complex with an inhibitor, ecotin, completed the initial structural picture for this enzyme, although much remains to be learned about its structure and biology (Gaboriaud *et al.*, 2013). It was previously shown that enzyme could cleave insulin growth factor binding protein-5 (Cortesio and Jiang, 2006) and one study has suggested that cleavage of this molecule might lead to the normal development afforded by the release of insulin growth factor from the binding protein (Sirmaci *et al.*, 2010), but no studies have been carried out to test this hypothesis and thus the crucial substrate for the enzyme in this context remains obscure.

It has been shown that MASP-1 and MASP-2 are both reasonably efficiently inhibited by C1-inhibitor in the absence of glycosaminoglycans (GAGs) (Dobo *et al.*, 2009; Kerr *et al.*, 2008). The presence of GAGs increases the rate of interaction of MASP-2 with C1-inhibitor by approximately 10-fold (Parej *et al.*, 2013), but it also increases the rate of interaction between antithrombin and the enzymes to a level where this serpin can also be considered a physiologically significant inhibitor of these proteases. Interestingly, α -2-macroglobulin has been shown to be irrelevant as a MASP inhibitor under physiological conditions. MASP-3 is not inhibited by any inhibitor identified to date.

The Alternative Pathway

The alternative pathway of complement activation (Figure 4) functions not only as a means of activating the system, it has also been postulated to be an amplification mechanism for the classical and lectin pathways.

The mechanism of activation of the alternative pathway is based upon the intrinsic instability of the thioester bond in C3 compared to its homologous counterparts, C4 and C5 (Pangburn and Rawal, 2002). The instability of the thioester bond in C3 means that this molecule spontaneously attaches itself to surfaces at a much greater rate than C4 and C5 (Pangburn *et al.*, 1981a,b). Unless the molecule is cleared, its attachment triggers the formation of a C3b-like conformation,

Figure 4 A schematic representation of the alternative complement pathway. Spontaneous C3 (PDB identifier: 2A73) turnover in blood or generated by the lectin or classical pathways results in the formation of C3a and C3b. C3b bound to a substrate binds the serine protease factor fB. This low-affinity complex is converted by the serine protease factor D (2XWB) into a C3-cleaving enzyme, C3bBb (2XWJ). This enzyme complex is stabilized by properdin (P). C3bBbP then cleaves C3 to C3a and C3b to complete the loop and lead to amplification. Since activation of the alternative pathway is spontaneous, regulators are particularly critical for preventing its excessive activation. Factor H, by binding to C3b, promotes the cleavage of the latter by the serine protease factor I to iC3b.

which in turn allows the attachment of factor B (fB) from the plasma. fB is homologous to component C2 of the classical and lectin pathways, with similar domain architecture of three N-terminal CCP domains linked to VWA and SP domains. Once bound to surface localized C3 or C3b, fB is activated by circulating factor D via cleavage between the third CCP domain and the VWA domain, much as occurs for the activation of C2 by C1s or MASP-2. Activated fB is referred to

as Bb and the C3bBb complex becomes a C3-convertase. Once stabilized by the binding of properdin, this C3 convertase is capable of cleaving further C3 molecules and thus allowing the surface of initial attachment to become decorated with C3b molecules that can attract further fB molecules. This mechanism therefore allows for activation of the alternative pathway or amplification of the other two pathways due to the central involvement of bound C3b molecules. Mammalian cells have a host of factors, such as decay-accelerating factor and complement receptor 1, that prevent or clear the initial attachment of C3 before it can bind the fB required to activate this pathway. This mechanism therefore provides an innate difference between foreign and host surfaces.

The C3bBb C3 convertase complex not only gives rise to further C3b molecules that can independently bind to the foreign surface, but a further molecule of C3b can associate with this complex. Since this extra C3b molecule provides a binding site for C5, the C3b₂Bb complex becomes a C5 convertase complex and thus can cleave C5 to form the C5b required to assemble the C6–C9 components into the MAC.

The mechanisms involved in the formation and action of the alternative pathway convertase complexes have been more studied than their classical/lectin counterparts (Forneris *et al.*, 2012). Much of the reason for this lies in the availability of molecules from bacteria and snakes that stabilize the alternative pathway complexes (e.g., Staphylococcal complement inhibitor (SCIN) molecule from *Staphylococcus aureus*) or bind to components of the complex in the same way as the human counterparts (cobra venom factor). The structure of the SCIN-stabilized C3bBb complex, for example, Rooijakkers *et al.* (2009) gave important insights into the assembly and molecular mechanisms underlying the operation of this complex in the activation of the alternative pathway. It was found that the Bb molecule bound to the C345 domain of the C3b via the N-terminal section of the VWA domain of Bb. The tight interactions between C345 and the VWA domain were not mirrored elsewhere, resulting in the Bb molecule essentially being free to ‘swing’ around this axis on the C3b molecule. This would allow it to be able to reach the scissile bonds in incoming C3 and eventually C5 molecules. The formation of a dimer between the C3 molecules in the unit cell of the crystals also pointed the way toward mechanisms whereby additional C3 molecules could bind to the C3b in the complex and thus be cleaved by the Bb component. Later work showed how factor D, which circulates in human plasma as a cleaved and activated form, was held in a disordered, inactive state until it bound to the C3bBb complex via an exosite on the factor D (Forneris *et al.*, 2010). The binding of factor D via its exosite caused an ordering of its active site such that it was able to cleave fB to yield activated Bb, which in turn allowed the C3bBb complex to act as a C3 convertase. Later work involving the solution of a structure of a complex between the C3-like cobra venom factor and C5 (Laursen *et al.*, 2011) showed how C5 was likely to be bound by C3b molecules in the convertase complexes and thus be presented for cleavage by Bb. The work on the alternative pathway complexes naturally also shed light on the likely mechanisms operative in the classical/lectin pathway convertase complexes.

Regulation of Complement Activation by Proteases and Binding Factors

Aside from the inhibition of C1r, C1s, MASP-1, and MASP-2 by C1-inhibitor, the complement system is highly regulated by a number of molecules. These molecules are particularly important to prevent unwarranted complement activation on host surfaces. The protease, factor I, associates with other regulators, such as factor H, bound to C3 and C4 and then cleaves them into inactive iC3b and iC4b forms (additional smaller forms, such as C3c and C4c can subsequently be formed). The enzyme consists of five domains: the N-terminal fl membrane-attack complex (FIMAC) domain, a scavenger receptor cysteine-rich (SRCR) domain, two low-density lipoprotein receptor (LDLRA) domains, and the serine protease domain. The enzyme is secreted in a cleaved form, but is inactive due to extensive disorder in its serine protease domain (Roversi *et al.*, 2011) that is maintained by the binding of the N-terminal region to the C-terminal serine protease domain. Binding of the enzyme to a C3b-factor H complex, for example, releases the N-terminal heavy region from the SP domain, allowing formation of the active conformation of the enzyme and thus promoting the cleavage of the C3b into inactive forms by the factor I.

Digestive Proteases: Roles in the Human Alimentary Tract

SG Bradley, Virginia Commonwealth University, Richmond, VA, USA

© 2016 Elsevier Inc. All rights reserved.

Glossary

Alimentary tract The mucus-lined muscular tube extending from the mouth to the anus; often used interchangeably with digestive tract or gastrointestinal tract.

Biofilm A thin layer of biological origin, usually containing bacteria, adhering to a surface that is exposed to an aqueous environment.

Bolus Food that has been chewed, mixed with saliva, and is ready to be swallowed.

Chyme Viscous fluid consisting of food partially digested in the stomach, and is ready to be passed into the small intestine.

Colon Major segment of the large intestine, including the ascending colon, transverse colon, descending colon and sigmoid colon but not the cecum, rectum and anal canal.

Endopeptidase A proteolytic enzyme that cleaves peptide bonds internally in a peptide rather than from the N- or C-terminus.

Fermentor A chamber for digestion and production of biological materials (such as antibiotics), often in the absence of air.

Heterodimer A molecule composed of two unlike subunits.

Homodimer A molecule composed of two like subunits.

Peristalsis Progressive waves of contractions that move digested food through the intestines during digestion.

Introduction

The digestive tract consists of several connected chambers, each serving unique functions. The various segments and chambers of this biological digester or fermentor are the sites of characteristic sequential processes that involve both enzymatic and physical activities (Vardakou *et al.*, 2011). Food enters the oral cavity and is processed for transfer to the stomach. The stomach is the first site of extensive proteolytic activity. The small intestine consists of three distinct segments anatomically: the duodenum, the jejunum and the ileum. The two segments of the small intestine nearer to the stomach, or proximal small intestine, are the sites of intense proteolysis and nutrient absorption. The distal small intestine, the ileum, continues the process of proteolysis, especially hydrolyzing peptides to free amino acids for absorption. The large intestine serves as a reclamation chamber, recovering water, and salts. The overall design and operation of the digestive tract resemble industrial processes used to produce antibiotics and therapeutic drugs. In both an industrial fermentor and the digestive tract there is a chamber where starting materials are mixed and prepared for the reaction chamber. Thereafter the product is recovered, and finally the waste materials are collected and eliminated. In human digestion of protein, the starting materials consist of exogenous substrates that are ingested periodically, supplemented by a steady addition of endogenous proteins as a result of release or secretion of proteinacious materials and cell shedding. The outputs of this integrated operation are the release and uptake of nutrients, the detoxification and elimination of waste materials, and the maintenance of the integrated system (Table 1). Proteolysis in the digestive tract releases bioactive peptides that act in the lumen or are absorbed (Chabance *et al.*, 1998) as well as peptides as a source of nutrients. In this article, the emphasis is on the key enzymes that release nutrients in foodstuffs. In addition, selected examples are described briefly of proteases that alter the activities of physiological active molecules such

as latent enzymes, chemokines, antigens and toxins and of proteases that serve to control biofilms interfering with absorption from or secretion into the lumen of the intestine (Johansson *et al.*, 2013). In addition to digestion by host proteases, microorganisms in the colon continue the hydrolysis of glycoproteins, polypeptides, oligopeptides, and nonprotein compounds with peptide bonds that have passed through the small intestine.

Role of the Oral Cavity in Proteolysis

Three processes critical for digestion of exogenous food occur in the oral cavity: (1) the teeth cut and grind the heterogeneous texture of ingested materials into smaller particles; (2) water and mucus are added as salivary secretions to make a somewhat viscous fluid that serves as a lubricant facilitating flow through the esophagus into the stomach; and (3) the digestive process is initiated by degrading starches and lipids that often coat food as a result of the preparation of meats or as an inherent part of the raw materials of vegetable proteins (Table 1). The 0.5–1.5 l of saliva secreted each day contains more than a thousand different proteins, most notably a number of amylases and lipases. Secreted saliva is slightly basic, pH 8, because of its sodium bicarbonate content, but the pH of masticated food decreases to pH 6 as carbon dioxide is released. The tongue acts as a mixing paddle and also has a role in moving the masticated food (bolus) into the pharynx and on to the esophagus. It is here that the respiratory tract and the digestive tract cross, creating the opportunity for food to be misdirected into the bronchus leading to choking.

The contents of the oral cavity include endogenous proteolytic enzymes and those produced by the oral microbial flora, an array of other proteins that serves as substrates, protease inhibitors, and antimicrobial products. The parotid gland secretions contain proline-rich proteins and secretory

Table 1 General description of the adult human digestive tract with an emphasis on protein digestion and amino acid absorption^a

Mouth	Stomach	Proximal small intestine	Distal small intestine	Colon/large intestine	Rectum
Maceration	Churning	Emulsification	Peristalsis	Resorption (H ₂ O)	Defecation
Lubrication	Acidification	Neutralization	Mucin shedding	Microbial flora	Microbial flora
2/3 cup volume	¼ cup to 1 quart	6–8 feet long	10–12 feet long	4.5 feet long	4 in. long
Held ca. 1 min	Retained 1–3 h	Flow through 2–3 h	Flow through 2–3 h	Held 15–20 h	Held 15–20 h
pH 6.5	pH 2	pH 6	pH 7.5	pH 5.7	pH 6.7
Mucosa lining	Protective mucus	Villi and microvilli	Villi and Microvilli	Invaginations/crypts	Mucus/muscular

	absorption		absorption	biotin	

^aData vary greatly according to age, gender, health status, and composition of the food.

Table 2 Important proteases in the digestive tract of humans

Enzymes	Enzyme types	Locations
Pepsin EC 3.4.23.1	Aspartic endopeptidase	Stomach
Trypsin isoforms EC 3.4.21.4	Serine endopeptidases	Duodenum primarily
Chymotrypsin isoforms EC 3.4.21.1	Serine endopeptidases	Duodenum primarily
Elastase 2A and 2B EC 3.4.21.71; 3A & 3B EC 2.4.21.70	Serine endopeptidases	Duodenum primarily
Carboxypeptidases 2A, 2B, 3B EC 3.4.17.1, EC 3.4.17.2	Metallo-exopeptidases	Duodenum primarily
Aminopeptidases EC 3.4.11.X; leucylaminopeptidase X=1	Metallo-exopeptidases	Jejunum and ileum
Dipeptidyl dipeptidase IV EC 3.4.14.5	Serine dipeptidase	Lymphatic vessels, ileum, etc.
Meprins A and B EC 3.4.24.18 and EC 3.4.24.63	Metallo-endopeptidase	Ileum and colon

immunoglobulin A in addition to amylases and lipases. The metalloprotease meprin has been identified on the luminal surfaces of parotid and submandibular glands (Craig *et al.*, 1991). The submandibular/sublingual gland secretions contain mucous glycoproteins, and the cysteine protease inhibitor cystatin (Zakhary *et al.*, 2007). About 2–4 g of salivary protein enter stomach each day, representing 4–8% of all proteins digested (Helmerhorst *et al.*, 2008). Salivary proteins that have a number of biological activities are the histatins, which are 3–4 kDa histidine-rich proteins secreted by both parotid and submandibular glands (Edgerton *et al.*, 2000). Histatins inhibit matrix metalloproteases, presumably by binding zinc and are potent inhibitors of aerobic bacteria and the pathogenic yeast *Candida albicans* (Sun *et al.*, 2009). Histatin 1 has been found to stimulate re-growth of epithelia and wound healing, thereby contributing to the integrity of the lining of the oral cavity (Oudhoff *et al.*, 2009).

Role of the Stomach in Proteolysis

Three processes critical for the digestion of endogenous and exogenous protein occur in the stomach: (1) the parietal cells produce hydrochloric acid bringing the food/saliva mixture to pH 2; (2) the 42 kDa proenzyme pepsinogen, produced by chief cells, partially unfolds in the acidic environment of the stomach allowing limited self-digestion that generates active

pepsin; and (3) the churning action of the stomach continues the process of homogenizing the stomach contents, which are periodically released into the first segment of the small intestine, the duodenum, as chyme (Gritti *et al.*, 2000). A thick mucus layer lines the stomach to protect epithelial cells from damage by HCl (Ermund *et al.*, 2013). At pH 2, the terminus of pepsinogen becomes accessible to the proteolytic active site of the molecule allowing the cleavage and release of a 44 amino acid sequence (Richter *et al.*, 1998). The resulting 34 kDa active pepsin is an aspartic protease that preferentially cleaves the peptide bond between hydrophobic and aromatic amino acid residues, resulting in polypeptides and oligopeptides rather than free amino acids. Pepsin was labeled as EC3.4.4.1 in 1961 and re-labeled as EC3.4.23.1 in 1972 (Table 2). An EC number is a system for identifying enzymes based upon the chemical reaction that they catalyze; for example, enzymes denoted as EC3.4 are hydrolases that act on peptide bonds (Rawlings and Salvesen, 2013). Pepsin is most active at pH 2 and relatively inactive above pH 6.5. In most young mammals, milk casein is initially processed by the aspartic protease chymosin (rennin), but human infants lack this enzyme even though the human genome contains a chymosin-related sequence (Kolmer *et al.*, 1991). In humans, casein in milk is precipitated by stomach acidity and then degraded by pepsin. There is limited absorption of oligopeptides generated in the stomach, such as kappa-caseinoglycopeptide, which is an inhibitor of platelet aggregation.

Role of the Small Intestine in Proteolysis

The duodenal epithelium produces bicarbonate to neutralize the hydrochloric acid in the chyme entering from the stomach. This protects the duodenal epithelium from direct damage and also makes the lumen favorable for the abundant digestive serine proteases, such as trypsin, released by the pancreas into the lumen (Rune and Viskum, 1969). The bile duct also empties into the duodenum, facilitating dispersion and emulsification of particles in the chyme. Bicarbonate concentration in the intestinal lumen determines pH, which is a key variable in enzyme activity, and also affects absorption and transport of nutrients (Davis *et al.*, 1980). The duodenum is only 10-in. long, but the epithelium is folded and covered with villi and microvilli, which amplify the effective absorptive surface by 20- to 50-fold. Digestion by serine proteases of oligopeptides to amino acids and absorption continue throughout the duodenum and jejunum (proximal small intestine). The transient time in the 6–8 foot proximal small intestine is about 2–3 h (Table 1).

Enteropeptidase (EC3.4.21.9) is a membrane-bound serine endopeptidase of the duodenal and jejunal brush borders (Zheng *et al.*, 2009). Enteropeptidase is produced as a proenzyme that is activated by other serine proteases such as duodenase (EC 3.4.21.23) or trypsin (Zamolodchikova *et al.*, 1995). Active enteropeptidase cleaves the specific trypsinogen activation peptide, Asp-Asp-Asp-Asp-Lys-Ile, to generate active trypsin. Following activation, trypsin cleaves and activates other proenzymes in the duodenum, including chymotrypsinogen, proelastase, and procarboxypeptidases (Lu *et al.*, 1997). Infants deficient in enteropeptidase develop diarrhea and edema, and fail to thrive (Holzinger *et al.*, 2002).

Trypsin (EC 3.4.21.4) is a 24 kDa serine endopeptidase, produced in the pancreas and secreted into the lumen of the duodenum. Actually three isoforms of trypsinogen are produced and each is activated by cleaving the carboxyl side of arginine and lysine residues (Szmola and Sahin-Tóth, 2007). Trypsin is the most abundant protease, constituting 19% of the protein in pancreatic secretions (Whitcomb and Lowe, 2007). Trypsin has a deep pocket with negatively charged amino acid residues at the bottom that favor binding of positively charged substrates. The catalytic amino acid residues of trypsin are His57... Asp102 ... Ser195, which are widely separated in sequence but conformationally brought together (Polgár, 2005). A proline residue on the carboxyl side of Lys or Arg prevents hydrolysis and an acidic residue on either side of Lys or Arg reduces the rate of cleavage. Trypsin undergoes autolysis to yield several active derivatives. Calcium is required for activation of trypsin (Cliffe and Grant, 1983) and for preventing autolysis leading to loss of proteolytic activity (Abbott *et al.*, 1975). The pH optimum for trypsin is 8, which is slightly more basic than its milieu in the duodenum and jejunum.

Chymotrypsin (EC 3.4.21.1) is a 26 kDa serine carboxypeptidase that preferentially cleaves the amide bond (the P₁ position) of an aromatic amino acid residues such as tyrosine, tryptophan and phenylalanine. Chymotrypsinogen constitutes 9% of the protein in pancreatic secretions (Whitcomb and Lowe, 2007). Chymotrypsin is produced as a 42 kDa proenzyme by acinar cells of the pancreas and released in vesicles, along with trypsin and a trypsin inhibitor, into the duodenum.

There are several isoforms of chymotrypsinogen having different substrate specificities and kinetics (Hudáky *et al.*, 1999) each of which is cleaved by trypsin into three segments that remain connected by S–S bonds. One of the isoforms, chymotrypsin C, degrades trypsinogen in the calcium-rich lumen of the duodenum and degrades trypsin in the calcium-poor lumen of the lower intestine (Szmola and Sahin-Tóth, 2007). The pH optimum and active site of chymotrypsin are the same as those of trypsin; that is, pH 8 and His...Asp...Ser, respectively (Polgár, 2005). Chymotrypsin has a deep cavity formed by hydrophobic amino acid residues, which accounts for the preference of the enzyme for peptide bonds containing tyrosine, phenylalanine or tryptophan (Hedstrom *et al.*, 1992).

Elastases 2A, 2B and 3B (EC 3.4.21.-) are endopeptidases produced in the pancreas as proenzymes that are activated by trypsin (Kawashima *et al.*, 1987). Humans have six loci coding for similar elastases that are differentially expressed throughout the body (Whitcomb and Lowe, 2007). Elastase 2A and 2B, which have 90% amino acid homology and similar conformations, cleave elastin-type proteins after Ala, Gly, Ser, Met and Phe residues. Elastase 3B has less proteolytic activity than elastases 2A and 2B. Consistent with the pH of the intestinal lumen, the optimum pH for elastases is 8.

Carboxypeptidases (CP) are zinc-containing exopeptidases that remove single amino acids from the carboxyl end of oligopeptides, many of which resulted from digestion of dietary proteins by pepsin, trypsin and chymotrypsin. Carboxypeptidases are produced in the pancreas as proenzymes that are activated by trypsin. Carboxypeptidase A (CPA) shows preference for terminal aliphatic or aromatic amino acids and has little or no activity on C-terminal Asp, Glu, Arg, Lys or Pro (Reverter *et al.*, 1997). In contrast, carboxypeptidase B (CPB) shows preference for basic C-terminal amino acid residues such as Lys and Arg. The differences in specificities between CPA and CPB can be attributed to the residues Ser205, Gly241, and Asp253 in CPB as compared to Gly207, Ile243, and Ile255 in CPA (Coll *et al.*, 1991). Carboxypeptidase O (CPO) shows preference for acidic C-terminal residues. CPA and CPB are found in the duodenum whereas CPO is located in the ileum.

Aminopeptidases (AP; EC subgroup 3.4.11.-) remove single amino acids (aminoacyl-peptide hydrolases) and dipeptides (dipeptidyl-peptide hydrolases) from the amino end of polypeptides. Many but not all aminopeptidases are zinc-dependent metallo-exopeptidases. Aminopeptidases are found in the cytoplasm and brush-border membrane of the intestinal epithelial and are released into the lumen as a result of cellular shedding. The optimum pH for aminopeptidases is between 7.5 and 8.5. As much as 30 g of mucosal cells are sloughed each day into the intestinal lumen (Freeman and Kim, 1978). The aminopeptidases in the jejunum originate in the cytoplasm of mucosal cells whereas the aminopeptidases in the ileum come from the brush-border membrane. Alanine aminopeptidase (EC 3.4.11.2), for example, is a glycoprotein in the distal ileum with a molecular mass of 118 kDa for the monomer, of which 12–21% of the mass is carbohydrate (McClellan and Garner, 1980; Sanderink *et al.*, 1988). Aminopeptidases are widely distributed throughout the body, but those in the intestinal tract are important in completing the digestion of proteins and peptides, allowing absorption of amino acids. This final processing of oligopeptides occurs both

at the cell surface and by cytosolic aminopeptidases (Sterchi and Woodley, 1980).

Dipeptidyl peptidase IV (EC 3.4.14.5; DDP-IV) is expressed on the surfaces of most cells in the body; however, it is enriched in the microvillus fraction of the distal ileum (Norén *et al.*, 1980). DDP-IV is a membrane-bound glycoprotein, acting as a serine protease, cell-surface marker and binding molecule (Misumi and Ikehara, 2004). DDP-IV is produced as an 88 kDa single chain of 766 amino acids that must form homodimers for optimum proteolytic activity. DDP-IV cleaves dipeptides from the N-terminus of peptides and proteins with a preference for cleaving Xaa-Pro dipeptides from polypeptides consisting of about 30 amino acids. DPP-IV has a wide range of substrates, including growth factors, chemokines, neuropeptides and vasoactive peptides (Kahne *et al.*, 1999). DDP-IV degrades vasoactive intestinal peptide, gastrin-releasing peptide and neuropeptide Y (Lambeir *et al.*, 2001), proteins such as gelatin and collagen (Green *et al.*, 2006) and atrial natriuretic peptide but not brain natriuretic peptide (Brandt *et al.*, 2006). DPP-IV cleaves glucose-independent insulinotropic polypeptide and glucagon-like peptide-1, incretins that are critical for glucose metabolism. DPP-IV is a key factor in the modulation of immune responses in the gut and other tissues. It is identical to the T cell activation antigen CD26 and to the adenosine deaminase binding protein (Drucker, 2007). DDP-IV is implicated in medical conditions as diverse as diabetes mellitus, obesity, tumor growth, and HIV infection (Engel *et al.*, 2003) and celiac disease (Martí *et al.*, 2005). Gluten, a protein in wheat and related cereal grains, when digested by pepsin/trypsin, generates proline-rich peptides with 10–50 amino acid residues as well as free amino acids and small peptides. Several of these proline-rich peptides have been found to elicit an inflammatory response in the small intestine. Indeed, about 1% of the American population develops this autoimmune disease in which the villi of the small intestine are damaged and absorption impaired. Another 6% of the American population experience symptoms similar to celiac disease but lack the antibodies and intestinal damage characteristic of this autoimmune disease; these individuals are said to be gluten sensitive or intolerant. DDP-IV has been implicated as the rate-limiting enzyme in the further degradation of immunogenic peptides that activate T cell responses in celiac patients (Hausch *et al.*, 2002). The only effective management of celiac disease and gluten sensitivity to date is elimination of gluten in the diet (Penagini *et al.*, 2013).

Meprin A and B (EC 3.4.24.18 and EC 3.4.24.63 respectively; PABA peptide hydrolase) are zinc metalloproteases that are abundant in the normal human small intestine, especially the brush border of the ileum and the intestinal lumen. Meprins are expressed by enterocytes as a dimer of alpha subunits lacking a membrane anchor and beta subunits with an anchor, linked by disulfide bridges (Leuenberger *et al.*, 2003). The alpha/beta dimers (heteromeric meprin A) and the dimers of beta subunits (meprin B) are retained at the cell surface. Both heteromeric meprin A and meprin B concentrate on the villi of the ileal brush border; however, meprin B can be shed from the cell surface. In contrast, the beta subunit is not expressed in the colon and intracellular proteolytic removal of the membrane anchor from the alpha subunit results in its secretion as homomeric soluble meprin A. The differential

expression of meprin alpha and beta subunits directs the proteolytic activity of the alpha subunit either to the brush-border membrane in the ileum or to the lumen in the colon (Lottaz *et al.*, 1999). The meprin subunits are expressed as 90 kDa glycoproteins that form inactive dimeric proenzymes that must be activated by a serine protease such as trypsin. The meprins act at neutral to basic pH values, and have the ability to digest a wide range of substrates found in the human diet and shed from the intestinal lining. For example, meprin A and B degrade extracellular matrix proteins, basement membrane proteins, cell junction proteins, azocasein, procollagen, gastrin, protein kinases, chemokines, and growth factors, with distinctive as well as overlapping substrate specificities. In addition, meprin activity has been correlated with monocyte migration and impaired epithelial barrier function (Bao *et al.*, 2013). Meprin B preferentially cleaves peptide bonds with negatively charged side chains of aspartic acid and glutamic acid, whereas meprin A cleaves peptide bonds with neutral aliphatic and aromatic side chains (Sterchi *et al.*, 2008). There are about 10^8 bacteria/gram of distal ileum tissue, kept at this low level compared to the 10^{12} bacteria/gram of colon tissue (Canny and McCormick, 2008) by the sloughing of biofilm and flushing action of the flow of fluid through the intestinal lumen. MUC2 mucin in the mouse small intestine is cleaved at the N-terminal end by meprin B, releasing the previously attached mucin (Schütte *et al.*, 2014). Meprins also degrade type 1 pili of *Escherichia coli*, thereby impairing its ability to invade the intestinal epithelium (Vazeille *et al.*, 2011). Celiac disease patients undergo a shift in expression of meprin from the duodenal epithelial cells to the lamina propria leukocytes. This shift correlates with development of marked duodenal inflammation of the mucosa after ingestion of gluten-containing cereals. (Lottaz *et al.*, 2007).

Role of the Large Intestine in Proteolysis

By the time ingested food reaches the large intestine about 5–8 h after ingestion, the proteins have been extensively digested and the amino acids and a few oligopeptides absorbed, leaving a watery indigestible sludge. Water is reabsorbed from the lumen of the small intestine to concentrate the digestive wastes. In addition, the large intestine contains a large and diverse array of facultative aerobic and anaerobic microorganisms that digest the waste material and produce B vitamins, including biotin, and vitamin K, which are absorbed (Canny and McCormick, 2008). The microbiome, which accounts for about half of the dry weight of feces, also produces gas (flatulence) by bacterial fermentation of residual nutrients. Epithelial sodium channels (ENaC) are abundant in the polarized epithelial cells of the colon, and are critical for maintaining the balance of Na^+ and K^+ balance in the body. The intestinal metalloprotease meprin B binds to, and stimulates ENaC activity (García-Caballero *et al.*, 2011). Meprins have been implicated in a number of intestinal diseases. Decreased meprin-alpha expression is associated with intestinal inflammation in inflammatory bowel disease (IBD) patients and in a mouse experimental model of IBD. Genetic analysis corroborate that MEP1A is a susceptibility gene for ulcerative colitis (Banerjee *et al.*, 2009). Meprin A is overexpressed in

colorectal cancer cells, leading to the suggestion that the pro-migratory and pro-angiogenic activity of meprin A may promote tumor progression (Lottaz *et al.*, 2011). The meprin-beta subunit is not expressed in the mouse colon but meprin B is present in the effluent from the small intestine and from macrophages entering the colon wall and lumen. Human meprin B sheds membrane-bound cytokines and growth factors, and also enhances inflammation and tumor progression (Arolas *et al.*, 2012).

Summary

The first stage of protein digestion occurs in the mouth where food is macerated and the protein made available for subsequent proteolysis. The Recommended Dietary Allowance for protein intake is 0.8 g/kg or 2 ounces for a 155 pound adult (Campbell *et al.*, 2002). In the stomach, the nutrient paste is exposed to hydrochloric acid that denatures and precipitates the proteins making them vulnerable to attack by pepsin liberating oligopeptides. The site of most active proteolysis is in the duodenum where bile is added to the chyme facilitating dispersion of particulate material, and trypsin and chymotrypsin extensively cleave proteins and polypeptides into oligopeptides and amino acids. Trypsin and chymotrypsin have complementary substrate preferences with the former cleaving Arg-Leu and Lys-X with X being any amino acid except proline, and the latter cleaving the carboxyl side of amide bonds of large hydrophobic amino acids. Carboxylases and aminopeptidases complete the digestion of proteins into amino acids, dipeptides and tripeptides that are readily absorbed in the duodenum and jejunum.

Digestive proteolysis is quite rapid with half of food leaving the stomach within 30 min and absorption nearly complete within 2–4 h after intake (Adibi, 1976; Akimov and Bezuglov, 2012). Free amino acids in the intestinal lumen are absorbed by the appropriate group-specific transport system: (1) neutral amino acids, (2) dibasic amino acids and cysteine, and (3) dicarboxylic amino acids (Silk *et al.*, 1985). Absorption of free amino acids is greater in the jejunum than in the ileum, which is the site of bile salt and vitamin B₁₂ absorption. Abundant Peyer's patches link the ileum to the immune system, sometimes with adverse consequences (celiac disease and ulcerative colitis). The large intestine serves as the waste collection and processing chamber, with reclamation of water, sodium ions, and bile acids.

Glossary

Allosteric site A site other than a protein's (usually enzyme's) active site, which affects its activity when an effector molecule binds to it.

Aspartic protease An enzyme cleaving peptide bonds in proteins that has an active site consisting of two closely spaced, coplanar aspartate residues that activate a water molecule for the hydrolysis reaction. Enzymes belonging to the AA clan of aspartic peptidases, typified by pepsin found in gastric juice, are present in most organisms higher than bacteria, as well as in retroviruses, where they are called retlopepsins and function as symmetric homodimers.

Bioavailability The fraction of an administered dose of a drug that reaches the systemic circulation, usually less than 100% in oral administration.

Diastereomer A stereoisomer of an optically active compound, in which the configuration of one or several chiral centers has been inverted (e.g., from *R* to *S*). Diastereomers should not be confused with (a pair of) enantiomers, in which the configuration of all chiral centers has been inverted. Consequently, enantiomers are mirror symmetric while diastereomers are not, and for this reason display different physical and chemical properties.

HIV (-1,-2) Human immunodeficiency virus (type 1 or 2), the causative agent of AIDS. The most common and virulent variant is designated HIV-1, whereas HIV-2 is more closely related to simian immunodeficiency virus and is less virulent.

HTLV Human T-cell leukemia virus, the first retrovirus to be associated with human disease (lymph node leukemia).

Integrase A virally encoded enzyme responsible for the incorporation of the double-stranded DNA copy of the retroviral genome into host cell genome. After integration, the infection is permanent and the infected cell cannot be cured.

Lipodystrophy A pathological condition characterized by abnormal or degenerative conditions or distribution of the body's fat.

M-PMV Mason–Pfizer monkey virus, a retrovirus similar to HIV, causing acquired immunodeficiency syndrome (AIDS)-like syndrome in macaque (rhesus) monkeys.

Nucleophile A chemical entity (such as a water molecule or hydroxyl group) rich in electrons, that is capable (usually after additional activation) of attacking another chemical group (such as the C atom of a peptide bond (O=C–N) with depleted electron density, during a chemical transformation, such as hydrolysis.

Pepstatin A universal inhibitor of aspartic proteases, originally isolated from cultures of various species of *Actinomyces*.

Retrovirus A virus with a single-stranded mRNA genome, which is reverse-transcribed into DNA in a process that inverts the normal flow (DNA→RNA) of genetic information.

Reverse transcriptase (RT) A virally encoded enzyme that produces a double-stranded DNA copy of a retroviral RNA genome. RT is an RNA-dependent DNA polymerase, with ribonuclease activity.

RSV Rous sarcoma virus, a retrovirus causing sarcoma in chickens. The first retrovirus to be described, over a century ago, by Peyton Rous. The currently preferred name is avian sarcoma virus (ASV).

Introduction

The emergence of the acquired immunodeficiency syndrome (AIDS) epidemic in the early 1980s and the subsequent identification of the human immunodeficiency virus (HIV) as its causative agent brought into focus the need to accelerate research on retroviruses, in order to assist the efforts to create anti-HIV drugs. No such drugs were available during the decade after the first reports of the new disease started appearing and initially the disease itself was invariably lethal since the retrovirus, which infects T4 leukocytes, devastates the immune system and leads to its complete failure. With lack of any treatment options, the outlook was obviously very grim.

Retroviruses have been known for over a century, since the identification of an infectious agent causing cancer in chickens, later named after its discoverer Rous sarcoma virus (RSV) (Rous, 1911). However, the exact nature of the agent, of its life cycle and the mode of infectivity were not established until much later. It is now known that the genetic material of retroviruses consists of single-stranded RNA of positive polarity (mRNA) that becomes transcribed into DNA in a reverse (or retro) transcription reaction that is catalyzed by a retrovirus-specific and virally encoded reverse transcriptase (RT). Another retroviral enzyme, integrase (IN), incorporates the resulting double-stranded viral DNA into the host genome, thus making the genetic material of the retrovirus (provirus) a permanent part of the infected cell.

One of the unusual characteristics of many viruses, including all retroviruses, is that their proteins are not translated as individual final units, but rather as one or more large polypeptides that need to be processed (cleaved) into the mature viral enzymes and structural proteins. In retroviruses, the enzyme responsible for such an activity is retroviral protease (PR). Analyzing the retrotransposon and retroviral genomic sequences, including human T-cell leukemia virus (HTLV) (closely related to HIV) and RSV, Toh *et al.* (1985) found a single copy of a signature sequence D(S/T)G (aspartate, serine or threonine, and glycine) in the translated proteins that could be matched with the active-site motif of aspartic proteases from the pepsin family. Pepsin and similar cell-derived aspartic proteases, however, contain this motif in two copies in their pseudo-twofold-symmetric active site, each contributed by a separate domain of a single polypeptide chain. To reconcile these puzzling observations, Toh *et al.* postulated the presence of a pepsin-like protease in retroviruses, with the caveat that the retroviral proteases would need to be symmetric homodimers composed of two identical subunits. This hypothesis was consistent with an earlier speculation by Tang *et al.* (1978) that cell-derived aspartic proteases have arisen from smaller proteins by gene duplication and divergent evolution. The postulate about the homodimeric nature of retroviral proteases (retropepsins) was experimentally confirmed when the crystal structure of RSV protease was determined (Miller *et al.*, 1989a).

Without a functional protease (which could be inactivated by mutation or by inhibitors) the retrovirus is still capable of replicating, but only immature viral particles can be formed, which are noninfectious, i.e., cannot infect other T4 cells or other patients. Although inhibition of HIV

PR does not cure the infection *per se*, it can be hoped that with prolonged treatment, inhibition of HIV PR will allow sufficient time for the elimination of the pool of the infected T4 cells.

Structure and Enzymatic Mechanism of HIV Protease

The structure of HIV-1 (type 1) PR itself, in unliganded state, was independently determined in 1989 by three groups (Navia *et al.*, 1989; Wlodawer *et al.*, 1989; Lapatto *et al.*, 1989). As in the case of RSV PR, HIV-1 PR is also a homodimer of two protein chains, 99 residues each. The protein fold of one subunit topologically resembles a truncated version of a single domain of pepsin, with the inter-subunit interface formed by four intertwined β strands from all termini (residues 1–4 and 95–99 from each subunit). The N-terminal strand is followed by two more β strands comprising residues 9–15 and 18–25, the latter including the catalytic Asp25. The next strand consists of residues 30–35 and is followed by a broad loop 36–42. Two more β strands, 43–49 and 52–58 form a flexible ‘flap’ loop that acts as a gating element for the active site. The second half of the HIV-1 PR subunit is topologically related to the first half and consists of β strands 52–66, 69–78, and 83–85. A prominent helix comprising residues 86–94 (absent in the N-terminal fold) has a clear counterpart in pepsins.

In the catalytic mechanism of aspartic proteases, a nucleophilic water molecule is activated by hydrogen bonding between the two (hemiprotonated) aspartate carboxylic groups. Such a catalytic water molecule was also found in the active sites of RSV PR (Miller *et al.*, 1989a) and HIV-1 PR (Wlodawer *et al.*, 1989) and its involvement in the enzymatic mechanism was gleaned from structural data (Jaskólski *et al.*, 1991).

Inhibitors of Retroviral Proteases

Strategies aimed at deactivation of HIV PR are focusing on relatively small chemical molecules that could inhibit its catalytic function. In a broad classification, the inhibitors can be covalent (irreversible) or non-covalent (reversible). Covalent inhibitors, such as molecules with a reactive oxirane (epoxy) group (Ro *et al.*, 1999) that attaches itself to the active-site aspartate, are not good candidates, even though they would block the enzyme permanently, because they can also modify many important host proteins. Non-covalent inhibitors typically compete with substrates for the active site, but bind more strongly and are resistant to cleavage. In the simplest approach, a competitive inhibitor is designed using as template the amino acid sequence of a good peptidic substrate (with some optimization), and replacing the scissile bond by a non-cleavable surrogate. Non-peptidic inhibitors use a similar strategy but the sequences of chemical moieties designed for docking in the respective enzyme binding sites do not have amino acid or peptidic character.

Whereas the structures of ligand-free retroviral proteases were crucial for delineating their structural and evolutionary relationship to pepsins, they were by themselves not sufficient to guide the design of potent inhibitors of HIV-1 PR.

Figure 1 Two canonical views of HIV-1 PR complexed with MVT-101, the first inhibitor cocrystallized with this enzyme. The main-chain traces of the two subunits of the enzyme are colored green and blue, and the ball-and-stick model of the inhibitor is in magenta. The molecular surface of the protein is shown in light blue, and the surface of the inhibitor in pink. In (a) the homodimeric enzyme is viewed along its twofold axis. In (b) this axis is vertical. Figure prepared by Dr. Jiri Vondrasek.

Figure 2 Chemical formulas of the peptide bond and its selected non-cleavable replacements.

Nevertheless, a model of an inhibitor complex was created on the basis of the structure of the apoenzyme of RSV PR superimposed on rhizopuspepsin, a fungal pepsin-like enzyme, in complex with a peptidic inhibitor with a reduced peptide replacing the cleavage site, His-Pro-Phe-His-Phe- ψ [CH-NH]Phe-Val-Tyr (where ψ denotes the reduced bond between the two Phe residues). Analysis of this model allowed successful delineation of seven subsites for the interactions between the side chains of the inhibitor and HIV-1 PR (Weber *et al.*, 1989).

Progress toward full understanding of the details of the interactions between the inhibitors of HIV-1 PR and the enzyme was boosted by the elucidation of the crystal structures of numerous complexes, now most likely going into thousands (although it is not possible to ascertain the exact count). The first such structure involved a complex with MVT-101 (Miller *et al.*, 1989b), a peptidic inhibitor created on the basis of a good natural substrate of HIV-1 PR with the sequence Ac-Thr-Ile-Met-Met-Gln-Arg.amide (K_m 1.4 mM) (Figure 1). In an

approach established previously for the synthesis of peptidic inhibitors of human renin (which is a pepsin-like aspartic protease involved in the blood pressure control cascade), both methionines in this inhibitor were replaced by norleucine isosteres, and the scissile peptide between them was replaced by a reduced analog. The inhibition constant K_i for MVT-101 was 0.78 μ M, indicating that this compound acted as a comparatively weak inhibitor and could not be considered as a good drug candidate, although it was powerful enough to form a stable complex with the protease during crystallization experiments.

Binding of MVT-101 led to quite substantial rearrangements of the structure of the enzyme, with the tips of the flaps, locked over the active-site-bound inhibitor, moving as much as 7 Å away from their positions in the free protease (where they were most likely fixed by crystal packing). In addition, in the complex with MVT-101 and all other peptidic inhibitors, a tightly bound water molecule was found at the interface

between the locked flap arms and the central part of the bound inhibitor, in variance with analogous pepsin-like complexes, where essentially only one flap is long enough to gate access to the active site. Although the HIV PR dimer is symmetric in the absence of a ligand with unique directionality, its binding induces some asymmetry which, if not transmitted to the surface during crystallization, leads to apparent twofold orientational disorder of the inhibitor that was noted in a number of structures. This binding, in turn, allowed delineation of the pockets that would accommodate the side chains of MVT-101. In the convention of [Schechter and Berger \(1967\)](#), in which the N-terminal (N-Pn...P1-) and C-terminal (-P1'...Pn'-C) substrate/inhibitor residues (linked by the P1-P1' scissile bond/analog) are docked in the corresponding Sn...S1...S1'...Sn' subsites of the enzyme, subsite S3 of HIV-1 PR included Arg8', Asp29', and Gly48'; subsite S2 was lined by Ala28', Ile47', Ile50', and Ile84'; and subsite S1 included Leu23', Asp25', Ile50', Pro81', Val82', and Ile84'. (Primed residues refer to the second subunit of the homodimer.) The subsites on the other side of the non-scissile P1-P1' bond were generally similar with few exceptions. Subsite S1' included Leu23', Gly27', Asp25', Ile50', Pro81', Val82', and Ile84'; subsite S2' consisted of Val32', Ile47', Gly48', and Ile50'; and subsite S3' was surrounded by Arg8', Gly27', Asp29', Gly48', and Val82'.

A large number of structures of complexes with other peptide-based inhibitors that included non-scissile peptide mimetics of different chemistry ([Figure 2](#)) followed, providing a wealth of information about the plasticity of the enzyme subsites. The structure of a complex with acetyl-pepstatin, in which the scissile bond was replaced by the unnatural amino acid statine, elucidated the binding of this standard inhibitor of cell-derived aspartic proteases to HIV-1 PR ([Fitzgerald et al., 1990](#)). Another early structure included a complex with JG-365, a hydroxyethylamine-containing peptide analog ([Swain et al., 1990](#)). The structural data on a large number of inhibitors and inhibitor complexes of HIV PR were previously summarized in detailed reviews ([Wlodawer and Erickson, 1993](#); [Fitzgerald, 1993](#); [Wlodawer and Vondrasek, 1998](#); [Qiu and Liu, 2011](#)).

First generation of HIV-1 PR Inhibitors Approved as AIDS Drugs

A complete summary of the status of the inhibitors of HIV-1 PR that have been approved for clinical use by the food and drug administration (FDA) can be found in Wikipedia. The first such inhibitor, approved on 6 December 1995, was saquinavir ([Figure 3](#)), developed by Hoffmann-La Roche. This compound, originally designated as Ro 31-8959, was the subject of intensive biochemical, biological, and structural studies ([Craig et al., 1991](#)). It has a molecular weight (MW) of 671. In common with JG-365, saquinavir utilizes hydroxyethylamine as a non-cleavable peptide isostere. However, early crystallographic studies ([Krohn et al., 1991](#)) suggested that the more potent version of this compound should be the *S* diastereomer of the -C*(OH)- chiral center, rather than the *R* form found in JG-365. Another major difference between these two compounds is the replacement of Pro, located in the P1' position of JG-365, by DIQ ((*S,S,S*)-decahydroisoquinoline-3-carbonyl) in saquinavir. The structure of a saquinavir

complex reported in 1991 ([Krohn et al., 1991](#)) was deposited in the Protein Data Bank only in 1996 and released in 1997 (PDB ID 1HXB), but a number of other structures using the native and mutant forms of HIV-1 PR became available since then, including the atomic-resolution (0.97 Å) structure ([Figure 4\(a\)](#)) of a complex with the V82A mutant (PDB ID 2NMZ; ([Tie et al., 2007](#))). The main problem with the original formulation of the drug (sold under the name of Invirase) was poor bioavailability, as low as 3–4%. However, the later re-formulation (brand name Fortovase) increased the bioavailability very significantly.

Three more inhibitors of HIV-1 PR gained FDA approval in 1996 and 1997 ([Wlodawer and Vondrasek, 1998](#)). Abbott Laboratories (now AbbVie) developed ritonavir (brand name Norvir), a relatively large (MW 721) peptidomimetic inhibitor ([Figure 3](#)) that was designed as a result of testing the concept of making the inhibitors fully, or nearly, *C*₂-symmetric. Even though ultimately such symmetric inhibitors turned out to be more difficult to manipulate for improved solubility and bioavailability, the concept resulted in the inclusion of a -CH₂-C(OH)- group as a non-cleavable linker between two phenylalanines that occupy the S1 and S1' subsites of the enzyme. Ritonavir has much better bioavailability than saquinavir, but it quickly became apparent that it had an unanticipated ability to act as a very potent inhibitor of cytochrome P450 (particularly of its isoform Cyp3A4), slowing down the removal of other pharmaceutical agents from circulation ([Lea and Faulds, 1996](#)). For that reason, ritonavir is currently used only as a booster for other protease inhibitors (see below).

Another peptidomimetic inhibitor of HIV-1 PR is indinavir ([Figure 3](#); brand name Crixivan), developed by Merck ([Vacca et al., 1994](#)). Slightly smaller (MW 614) than either saquinavir or ritonavir, it utilizes a hydroxyethylamine insert as a non-cleavable group. The compound is highly selective for HIV-1 PR (K_i 0.52 nM) and HIV-2 PR (K_i 3.3 nM) while it shows no inhibitory activity against any mammalian (including human) aspartic proteases.

An inhibitor that finally shed any peptidic character is viracept ([Figure 3](#); brand name Nelfinavir). Although this drug utilizes the same DIQ group at its 'C terminus' as saquinavir, it does not retain any actual peptide bonds. Viracept was developed by Agouron Pharmaceuticals ([Kaldor et al., 1997](#)), a company, now part of Pfizer, especially created with the task of introducing structure-based drug design ([Appelt et al., 1991](#)). Viracept is smaller (MW 568) than the previous approved inhibitors of HIV-1 PR and was the first protease inhibitor approved for the treatment of pediatric AIDS.

The next inhibitor to reach the market, amprenavir ([Figure 3](#); brand name Agenerase), was originally discovered at Vertex Pharmaceuticals, another venture capital company explicitly created to apply rational structure-based drug design in practice. The company was later acquired by GlaxoSmithKline, which became the distributor of this drug. Amprenavir is smaller still (MW 506) than the previous drugs but it was withdrawn from the market in 2004 after introduction of its prodrug form, fosamprenavir (brand name Lexiva (US) or Telzir (Europe)), in which a main-chain hydroxyl group was modified by phosphorylation. The prodrug is converted to amprenavir by host enzymes, thus slowing the release (and excretion) of the active form.

Figure 3 Chemical formulas of the 10 FDA-approved inhibitors of HIV-1 PR.

Emergence of Resistance to Clinical Inhibitors of HIV-1 PR

Since the RT enzymes of retroviruses lack proofreading mechanism, the error rates in transcription are very high, estimated at

1:10 000 for HIV-1 (Katz and Skalka, 1990). Such an elevated level of mutations indicates that every possible variant of the retroviral genome has already been transcribed in an infected patient treated with protease inhibitors (or, for that matter, with any other anti-AIDS therapy). Thus, development of resistance is

Figure 4 Hydrogen-bond interactions between HIV-1 PR and selected inhibitors. Hydrogen bonds are indicated by dashed lines. Interactions mediated by water molecules are shown in red. (a) Hydrogen-bond interactions between HIV-1 PR and saquinavir, based on the atomic-resolution structure of the complex (PDB ID 2NMZ). (b) Hydrogen-bond interactions between HIV-1 PR and darunavir, seen in an atomic-resolution crystal structure (PDB ID 2HS1). Figure prepared by Dr. Jerry Alexandratos.

just a matter of days, since what is required is only selection of preexisting variants of the virus, rather than mutagenesis subsequent to exposure of the virus to challenging drugs. This problem was noticed early on and became clearly evident in the early clinical studies. Indeed, [Condra *et al.* \(1995\)](#) showed that patients subjected to experimental monotherapy using only indinavir, developed resistance not only to this particular inhibitor, but also to other drugs that inhibit HIV-1 PR, including saquinavir, amprenavir, and ritonavir. The authors stated that “These observations reflect the common nature of the inhibitors’ target and suggest that combination therapy with multiple protease inhibitors may yield multiply resistant variants. In addition, initial therapy with any one inhibitor may limit the benefit of subsequent treatment with the remaining compounds.” It is significant that these observations were published even before the approval of the first of these drugs by the FDA, thus the need for multidrug therapy combining different classes of targets (such as RT and IN) and for the development of novel protease inhibitors that would be less effective in eliciting viral resistance, was apparent already early on.

One of the most common mutations in HIV-1 PR exposed to the first-generation inhibitors is replacement of Val82 by either threonine or alanine. The structure of a complex of HIV-1 PR with ritonavir was used at Abbott to guide synthesis of a new inhibitor, lopinavir ([Figure 3](#); [Sham *et al.*, 1998](#); [Hurst and Faulds, 2000](#)) that would not interact with residue 82 at all despite its comparatively larger size (MW 629 – still smaller, though, than the parent compound ritonavir). The problem with lopinavir, however, was its very short half-life in plasma, no longer than 2–4 h. However, combination of therapeutic amounts of lopinavir with subtherapeutic quantities of ritonavir extended the half-life of the drug very significantly. The form of lopinavir approved by the FDA is such a combination (brand name Kaletra).

Atazanavir ([Figure 3](#); brand name Reyataz), developed at Bristol-Myers Squibb, is another FDA-approved inhibitor of predominantly peptidic character ([Robinson *et al.*, 2000](#)), but with unexpectedly long half-life in plasma, allowing for once-a-day dosing. Although not explicitly designed to combat resistance, it is nevertheless quite successful in this regard, especially if

boosted with ritonavir. An advantage of atazanavir over other inhibitors of HIV-1 PR is that it causes fewer side effects, in particular it is less likely to cause lipodystrophy and elevate cholesterol levels.

Tipranavir ([Figure 3](#); brand name Aptivus), developed at Boehringer-Ingelheim, is a non-peptidic protease inhibitor originally synthesized at Upjohn as part of a structure-based discovery program ([Thaisrivongs and Strohbach, 1999](#)). It is administered in combination therapy with ritonavir to treat particularly difficult HIV infections. Tipranavir is successful in inhibiting the replication of viruses that are resistant to other protease inhibitors and it is recommended for patients not responding to other treatments. Development of resistance to tipranavir itself requires several simultaneous mutations of the HIV-1 PR sequence. In one study, as many as 10 mutations were required to decrease tipranavir’s inhibitory potency by two orders of magnitude ([Doyon *et al.*, 2005](#)).

The most recent among the FDA-approved inhibitors of HIV-1 PR and most often used in current clinical practice is darunavir ([Figure 3](#); brand name Prezista), developed at Tibotec/Johnson and Johnson. It is a non-peptidic compound with MW 548 and the K_d value of 4.5 pM, the latter significantly lower than for other inhibitors of HIV-1 PR ([Koh *et al.*, 2003](#)). It is also commonly administered in combination with ritonavir, in order to increase its plasma half-life. The hydrogen bonded interactions between darunavir and HIV-1 PR are shown in [Figure 4\(b\)](#).

Roads Not Taken – Inhibitors of HIV-1 PR That Did Not Become Drugs

Whereas the clinically relevant inhibitors of HIV-1 PR represent a triumph of rational drug design, many other compounds have been created as either intermediate steps of their development, or as testing grounds for the utilization of innovative chemical principles. Thus, for example, many fully twofold symmetric inhibitors were found to be quite potent, although they never became drugs ([Kempf *et al.*, 1994](#)). Some of the symmetric designs included an additional retropepsin-specific feature, namely a mimic of the water molecule that mediates the interactions

between the flap loops and the central region of the peptidic inhibitors or substrates. A way to accomplish this dual goal was to utilize cyclic urea derivatives as the central part of the inhibitors. Several very potent inhibitors, such as DMP-450 and DMP-323 resulted from these approaches, but for a variety of reasons, some of them commercial rather than scientific, they did not progress to become clinical drugs (Lam *et al.*, 1994).

One of the earliest attempts to use structural information for rational design of HIV-1 PR inhibitors was a computational experiment that led to the identification of haloperidol, a compound related to a known antipsychotic agent bromoperidol, as a potential inhibitor of this enzyme (DesJarlais *et al.*, 1990). This was an interesting early discovery of a non-peptidic compound which, however, did not lead to its practical application as an antiviral agent, mainly because the required concentration of haloperidol would exceed by several orders of magnitude the doses of bromoperidol administered in psychiatric treatment.

Considerable efforts went into modification of the successful inhibitors of HIV-1 PR that would lead to easier and more efficient synthesis. An example is provided by the modification of amprenavir, in which the non-cleavable isostere of the peptide bond was replaced by 1,2,3-triazole. Such compounds could be produced by fast and high-yield azide-alkyne click chemistry and were shown to be excellent inhibitors of both the native and mutant enzymes (Brik *et al.*, 2005).

A very attractive chemical procedure that used solid-state synthesis of 4-aryl-1,4-dihydropyridines as precursors of C₂-symmetric cage compounds (Hilgeroth *et al.*, 1999, 2002) with inhibitory properties against HIV PR, has never been developed beyond preliminary tests. Also other novel compounds that were not only non-peptidic, but even non-carbon, called carboranes, have not been developed in practice, although they appeared promising in preliminary studies (Cigler *et al.*, 2005).

Where Will the HIV-1 PR Inhibitors Be in the Future?

Detailed studies of not only inhibitor complexes cocrystallized with active HIV-1 PR, but also of substrate peptides bound to inactive enzyme (usually variants with the catalytic Asp25 mutated to asparagine) led to the definition of the concept of 'substrate envelope' – the minimum volume occupied by parts of the majority of efficiently processed substrates of the enzyme (Prabu-Jeyabalan *et al.*, 2002). The postulate was that an inhibitor that does not extend much beyond such an envelope is unlikely to be resistance-prone, since any mutations interfering with its binding would also prevent efficient processing of legitimate substrates. Based on this principle, a number of new inhibitors with nanomolar potencies against patient-derived wild-type viruses from HIV-1 clades A, B, and C, as well as their multidrug resistance (MDR) variants, were synthesized and tested (Parai *et al.*, 2012). In that work, introduction of cyclic and acyclic P2 carbamates with multiple hydrogen-bond donor and acceptor centers resulted in the creation of highly potent inhibitors of HIV-1 PR.

Another important concept applicable to the design of 'resistance-resistant' inhibitors is targeting the protein backbone. It was speculated that inhibitors that maximize their interactions in the HIV-1 PR active site, particularly through multiple hydrogen bonds with the protein backbone of wild-type HIV-1

protease, would maintain those contacts with mutant proteases as well. Targeting the sequence-independent protein backbone rather than the sequence-specific side chains, should therefore curtail the emergence of drug-resistant variants of HIV, as mutations that alter the backbone conformation would most likely reduce or abrogate the catalytic capacity as well (Ghosh *et al.*, 2012).

Fragment screening is a method of searching for compounds capable of even weak binding to the target proteins, with the aim of ultimately increasing their avidity through connecting two or more such 'fragments' covalently. This approach has also been applied to HIV PR, mostly with the aim of finding molecules that would bind to allosteric sites distant from the active site, interfering with such obligatory property as dimerization. Binding of components of suitable cocktails (i.e., chemical libraries) of such test compounds could be monitored by crystallography or, for example, by surface plasmon resonance. Although these studies yielded some interesting preliminary results, they did not lead so far to practical applications (Bauman *et al.*, 2012).

Most of the approaches to inhibitor design treat the target enzyme as a rigid object. However, consideration of the inherent flexibility of protein chains is becoming increasingly important and has already been utilized in the design of inhibitors of HIV PR (Lukman *et al.*, 2014). Another novel concept involved replacement of some non-exchangeable hydrogen atoms in the inhibitor molecule by deuterium. Deuterated compounds are metabolized more slowly, thus allowing prolonged maintenance of their effective blood levels. Such an approach was tested on a modification of atazanavir named CTP-518 (GlaxoSmithKline/Concert Pharmaceuticals). Whereas preclinical studies demonstrated that this modification retained the antiviral potency and increased the half-life and plasma trough levels, the results of Phase I clinical trials, initiated in 2009, have not been reported.

Interference with dimerization is a very attractive approach to HIV PR inhibition because it would prevent the formation of a viable enzyme in the first place (Boggetto and Reboud-Ravaux, 2002). Dimerization inhibitors would have to be extremely potent because the dissociation constant of HIV-1 PR is very low, which also hinders structural studies of this protein in monomeric form. The latter obstacle could be circumvented by looking at similar enzymes from other retroviruses (such as Mason-Pfizer monkey virus (M-PMV)), which can be crystallized as monomers (Khatib *et al.*, 2011; Gilski *et al.*, 2011). Interestingly, it appears that darunavir is capable of acting not only as a very potent competitive inhibitor of HIV-1 PR, but is also able to interfere with the dimerization equilibrium of the enzyme (Hayashi *et al.*, 2014).

Whereas it is not certain which of the novel approaches to the design of inhibitors of HIV-1 PR will lead to new and more potent AIDS drugs, the multitude of experimental approaches bodes well for the future success in creating compounds with novel mode of action and lower potential for triggering resistance. The last word has clearly not yet been said.

Glossary

Angioedema The rapid, and potentially fatal, swelling (edema) of the dermis, subcutaneous tissue, and mucosa and submucosal tissues. It can be caused through an allergic reaction or be inherited. It is a rare side effect of ACE inhibitor therapy in the treatment of hypertension.

Treatment can range from use of antihistamines or steroids, through to adrenaline in severe cases.

Baroreflex The baroreflex or baroreceptor reflex is a homeostatic mechanism used by the body to maintain a constant blood pressure.

Endopeptidase An endopeptidase is a proteolytic enzyme that cleaves a peptide bond within a peptide or protein sequence but not at the termini. Examples would include trypsin, chymotrypsin, and neprilysin.

Endothelium The endothelium is a cell layer lining the interior surface of blood and lymphatic vessels. The

endothelium is composed of endothelial cells and those in direct contact with the blood are referred to as vascular endothelial cells.

Exocytosis A highly regulated, cellular mechanism for the secretion of protein and other cellular constituents contained in secretory vesicles within the cell. It can either be a constitutive process or triggered by extracellular signals.

Natriuretic A natriuretic agent is one that causes sodium excretion in the urine via the action of the kidneys.

Zymogen A zymogen is an inactive enzyme or hormone precursor. An example of a proenzyme zymogen would be trypsinogen (converted to active trypsin), and of a prohormone, proinsulin (converted to Insulin). The activation is carried out by proteolytic enzymes.

Introduction

Blood pressure homeostasis is maintained principally by circulating small peptides generated by a highly ordered cascade of proteases. Disruption of this cascade is a major pathological step in the development of cardiovascular disease, which is the leading cause of death in the developed world. In a healthy individual, blood pressure maintenance is a finely tuned balance. Simply standing causes a drop in blood pressure that must be counteracted to avoid fainting. The cardiovascular system responds to this change by constricting the peripheral vessels and increasing heart rate. In pathological conditions this balance is chronically disrupted; with hypotension the organs do not receive sufficient oxygen or nutrients and as a result have compromised function which can, over sustained periods, lead to permanent damage. Conversely, in hypertension, the circulating pressure causes vascular stress and kidney dysfunction. It is estimated that 1 billion people worldwide suffer from hypertension and 13.5% of premature deaths globally are attributed to it (Lawes *et al.*, 2008). It is generally recognized that around 30% of the normal variation in blood pressure is attributable to genetic factors with around 50% being due to environmental factors.

For the most part, the sympathetic nervous system controls blood pressure. A fall in arterial pressure is detected by the baroreceptors. The baroreflex acts to compensate for the change in pressure by stimulating an increase in sympathetic and a decrease in parasympathetic nerve activity, as well as the release of hormonal mediators of blood pressure such as the peptide, vasopressin, which reduces urine output in the kidney and causes vasoconstriction. Sympathetic nerve activity stimulates the release of adrenaline. Adrenaline acts through the β_1 adrenergic receptors in cardiac tissue to affect cardiac

output and ventricular contractility. Under most circumstances adrenaline causes an increase in blood pressure partly through vasoconstriction of the vascular beds and vasodilation of the vessels in skeletal and cardiac muscle. The baroreflex therefore works to maintain a constant blood pressure under normal conditions. Hypertension develops slowly over a long period of time, resulting from a loss of baroreceptor sensitivity, such that the receptors reset at a new higher pressure. The baroreflex still works to maintain 'normal' pressure; however, normal now refers to a hypertensive state.

Proteolytic Regulation of Blood Pressure

The Renin-Angiotensin System (RAS)

Overview of the system

The key proteolytic cascade regulating blood pressure is the RAS. The RAS links brain and kidney control of blood pressure by controlling fluid and electrolyte balance. The RAS is composed of peptides derived from precursor peptides/proteins which undergo successive cleavage by the enzymes (proteases) within the system. As such, the RAS is able to fine tune blood pressure via a highly ordered endocrine cascade. The RAS acts to increase blood pressure, primarily by producing the vaso-pressor octapeptide, angiotensin (Ang) II, in a pathway which has been thoroughly characterized over more than 60 years. Ang II also promotes tissue remodeling in various organs, especially heart and kidney. The classical pathway begins with the precursor protein angiotensinogen, from which the inert decapeptide, Ang I, is cleaved and this, in turn, is then converted to Ang II by angiotensin-converting enzyme (ACE). ACE inhibitors have been the first line of treatment against hypertension for decades now and their success has served to place

ACE and its biologically active product, Ang II, as central regulators of the RAS.

Our knowledge of this over-simplistic linear RAS pathway has evolved in recent years into a far more complex and regulated system with multiple biologically active peptide components. Two principal discoveries drove these developments: the emergence of a role for the vasodilatory peptide Ang-(1–7) and the discovery of its biosynthesis from Ang II by the ACE homolog, ACE2, together providing a counterbalance to the actions of Ang II (Campagnole-Santos *et al.*, 1989; Tipnis *et al.*, 2000). Ang-(1–7) can also be generated from Ang I by another zinc peptidase, neprilysin (NEP) (Rice *et al.*, 2004).

The major actions of Ang II are effected through the angiotensin II type 1 receptor, AT₁R, which is a G-protein coupled receptor that mediates increases in blood pressure through a variety of mechanisms, which include vasoconstriction, renal sodium reabsorption, aldosterone and vasopressin secretion, and activation of hypothalamic neurons to stimulate thirst and hence fluid uptake. The second, less widely expressed receptor for Ang II is the related AT₂R, which mediates generally opposing effects to those of the AT₁R causing vasodilation, inhibition of hypertrophy and fibrosis (Carey *et al.*, 2000). The most well-established roles of Ang-(1–7) are thought to be mediated through its own specific receptor, termed Mas (Santos *et al.*, 2003) opposing the actions of Ang II that are mediated through the AT₁R. While AT₁R antagonists such as losartan are widely used in the treatment of hypertension and vascular disease, AT₂R or Mas receptor agonists may provide alternative therapeutic strategies. Likewise, up-regulation of ACE2 levels or activity could be cardioprotective.

Another fork in the pathway mediated by aminopeptidase A generates the peptide Ang III directly from Ang II. Ang III interacts with both AT₁R and AT₂R with similar affinity to Ang II and appears to have a key role in the brain RAS controlling blood pressure (Marc and Llorens Cortes, 2011). The action of aminopeptidase N on Ang III generates Ang IV which increases renal blood flow, decreases tubular sodium transport and also has central nervous system actions, having an influence on memory and acting through a receptor which is itself a protease – the insulin-regulated aminopeptidase (IRAP), inhibitors of which have actions as cognitive enhancers (Albiston *et al.*, 2011). Most recently, two new functional peptides in the RAS have been identified: angiotensin A, derived by decarboxylation of Ang II (Jankowski *et al.*, 2007), and alamandine produced from either Ang A or Ang-(1–7) (Lautner *et al.*, 2013). These interlinked pathways are summarized in Figure 1.

RAS proteases

From angiotensinogen to Ang I: renin

Angiotensinogen, a glycoprotein secreted by the liver into the bloodstream, is the immediate precursor of Ang I which is cleaved proteolytically from its N-terminus by renin, in the rate-limiting step of the RAS cascade. Renin is initially synthesized in a zymogen form, prorenin, and is stored in secretory granules in the kidney. Prorenin is both constitutively secreted and subject to regulated exocytosis in response to stimuli and it accounts for 70–90% of circulating renin. The

Figure 1 The complex network of the RAS. The precursor protein, angiotensinogen, secreted from the liver, is cleaved by the renal enzyme renin to generate the inactive decapeptide Ang I released from its N-terminus. ACE converts Ang I to the vasoregulatory octapeptide Ang II which acts through two types of G-protein coupled receptors, AT₁R and AT₂R. Ang II can also be converted to the counter-regulatory heptapeptide, Ang-(1–7), predominantly by ACE2, although an alternative but minor pathway exists from Ang I and Ang-(1–9). Other Ang products can also be formed, including Ang III, Ang IV, Ang-(1–7), and alamandine, which act through their own respective receptors (AT₁R/AT₂R for Ang III in brain (not shown), IRAP for Ang IV, Mas for Ang-(1–7), and MrgD for alamandine (see text for details)). ACE, angiotensin-converting enzyme; Ang, angiotensin; AP-A, aminopeptidase A; AP-N, aminopeptidase N; NEP, neprilysin; PEP, proline endopeptidase.

conversion of prorenin to renin involves the removal of a 43 amino acid peptide from its N-terminus that obstructs the active site. This activation can be facilitated by multiple pathways: enzymic cleavage, which results in irreversible activation of renin; propeptide unfolding that occurs at low temperature or pH resulting in reversible conversion, or via the action of the prorenin receptor (PRR) that results in reversible activation. Proteases capable of cleaving the prorenin propeptide include proconvertase I, kallikrein and cathepsin B. Activation of prorenin resulting from binding to the PRR allows spatial control of the conversion at the cell-surface (Nguyen *et al.*, 2002). However, the main function of the PRR may not relate to the RAS but to other quite distinct signalling pathways (Nguyen, 2011).

A big question in the RAS field has been whether the generation of Ang II *in vivo* in humans can involve enzymes or pathways other than those employing renin and ACE. The observation that renin and prorenin knockout mice lack detectable plasma levels of Ang I, and the effects of renin/prorenin deficiency in humans, establish a predominant role for renin in Ang I generation. Renin inhibitors also effectively suppress levels of Ang I and Ang II. However, ACE-null mice do have detectable circulating Ang II levels implying other enzymes may be able to compensate. One enzyme that could contribute to this process is the serine protease, chymase, and some studies indicate that chymase may be important in

Ang II generation, particularly in the human heart (Urata *et al.*, 1990). However, most clinical evidence currently supports the concept that renin, together with ACE, predominate in human Ang II generation although, at some sites and in certain pathological circumstances, other enzymes and particularly chymase, may be relevant (Campbell, 2012).

From Ang I to Ang II: ACE

The ACE and ACE2 are both zinc metallopeptidases. This metal ion activates a water molecule which then acts as a nucleophile to hydrolyze the peptide bond of their respective substrates. Members of this peptidase family are primarily exopeptidases, acting near the C-terminus of their oligopeptide substrates. These two enzymes have additional noncatalytic roles that will not be focused on in this article but have been well described elsewhere (Clarke *et al.*, 2012; Gonzalez-Villalobos *et al.*, 2013; Kuba *et al.*, 2013).

The ACE protein exists in two forms, the somatic form (sACE), expressed on the surface of vascular endothelial, epithelial and neuroepithelial cells, and the testicular form (tACE) present only in germinal cells and which regulates male fertility. The two isoforms are the result of tissue-specific promoter sequences within the ACE gene (Soubrier *et al.*, 1988; Hubert *et al.*, 1991). sACE has two catalytic sites (N- and C-domains) thought to be the result of a gene duplication, whereas the tACE contains only one of these sites (Hubert *et al.*, 1991).

ACE has a broad substrate specificity acting both as a peptidyl dipeptidase (i.e., releasing a C-terminal dipeptide from its substrates) as well as an endopeptidase and, in addition to Ang I, it can hydrolyze bradykinin, substance P, neurotensin, and a number of other peptide substrates *in vitro*, including the hemoregulatory and anti-fibrotic tetrapeptide, acetyl-Ser-Asp-Lys-Pro (AcSDKP; Rieger *et al.*, 1993). The two catalytic domains of ACE have differing substrate specificities (Gonzalez-Villalobos *et al.*, 2013). Angiotensin I and the counter-regulatory vasodilator bradykinin are substrates for both catalytic sites of ACE, although Ang II is more efficiently formed by the C-terminal domain. In contrast, AcSDKP is a substrate only for the N-terminal site of ACE and thereby affects inflammation and organ fibrosis. The activities of ACE are chloride-dependent, which is due to the presence of two distinct chloride binding sites (CL1 and CL2) located approximately 20 Å apart in ACE (Yates *et al.*, 2014).

ACE is subject to posttranslational regulation being released from the plasma membrane by proteolytic shedding (Hooper *et al.*, 1987). In fact, ACE was initially isolated from plasma in its shed form before the identification of its primary existence as a transmembrane, cell-surface enzyme (Skeggs *et al.*, 1956). The constitutive shedding of ACE is performed by an as yet unidentified zinc-dependent secretase or sheddase (Parvathy *et al.*, 1997). Such shedding events are commonly mediated by a disintegrin and metalloproteinase (ADAM) proteases, particularly ADAM10 or 17 (van Goor *et al.*, 2009) but this is not the case for ACE (Allinson *et al.*, 2004). However, under certain stimulated conditions ADAM9 may contribute to the shedding (English *et al.*, 2012). One regulator of the shedding event is the calcium-binding protein calmodulin, which binds to the cytoplasmic tail of ACE, and calmodulin

inhibitors stimulate the shedding of ACE (Chattopadhyay *et al.*, 2005).

ACE inhibitors as antihypertensive drugs have become one of the most successful rational therapeutic developments in biomedical science. Peptide inhibitors of ACE were first isolated from snake venom in 1965 and their cardiovascular effects demonstrated (Ferreira and Rocha e Silva, 1965). The first non-peptide inhibitor of ACE based on these studies, captopril, was developed in 1977 (Ondetti *et al.*, 1977) and entered clinical use in 1981. Unfortunately, due to the presence of a zinc coordinating thiol group, captopril had significant side effects, including development of a rash and taste disturbances. Other inhibitors were subsequently developed based on the structure of captopril but used different zinc coordinating groups. For example, lisinopril and enalaprilat, in which the thiol group of captopril is replaced by a carboxylate group. These too, although very effective in blood pressure control, do still have some side effects, partly because of their lack of catalytic domain specificity, most notably a persistent cough in 5–20% of patients and, more seriously, angioedema in 0.1–0.5% of patients (Morimoto *et al.*, 2004). The occurrence of angioedema is probably due to inhibition of bradykinin catabolism by ACE, resulting in the persistence of bradykinin and its vasodilatory and vascular permeability properties. The 3D structure of ACE was solved over a decade ago and subsequent structural studies are now allowing the development of a new generation of highly selective ACE inhibitors targeted against either the N- or C-domain of the enzyme (Natesh *et al.*, 2003; Douglas *et al.*, 2014). ACE inhibitor development has been widely reviewed elsewhere (see e.g., Anthony *et al.*, 2012).

While specific renin inhibitors reduce Ang II levels they do not affect the levels of other ACE substrates such as bradykinin and substance P which contribute to some of the side effects of ACE inhibitor use. Hence, inhibiting renin as the first and rate-limiting step would at first sight appear a better therapeutic option to block Ang II formation selectively than the use of ACE inhibitors. Furthermore, renin inhibition avoids ACE-independent pathways from Ang I to Ang II (e.g., chymase). Renin is an aspartic protease and, as such, designing specific and selective renin inhibitors has proved extremely difficult. However, aliskiren is proving its efficacy as the newest antihypertensive drug and the first orally active, clinically available renin inhibitor (Friedrich *et al.*, 2013).

Despite intensive investigation of the role of ACE in the development of hypertension and cardiovascular disease, relatively little is known about the signals that regulate vascular ACE expression levels. One such factor is that of fluid-induced shear stress, the drag force acting on the endothelium as a result of blood flow, and which plays a critical role in the development of endothelial atherosclerosis. This effect is mediated via the adenosine monophosphate (AMP)-activated protein kinase (AMPK) and involves posttranscriptional regulation by certain microRNAs (miR-143/145) (Kohlstedt *et al.*, 2013). There is additional evidence that the translation of ACE is regulated by these and other microRNAs in vascular smooth muscle cells and elsewhere (Fernandes *et al.*, 2011). There appears to be a strong influence of epigenetic mechanisms on sACE expression involving both DNA methylation and histone acetylation (Rivière *et al.*, 2011). Probably the

most studied aspect of ACE genetics and expression is the occurrence of an insertion/deletion (I/D) polymorphism in the ACE gene which is a major locus that determines plasma and tissue ACE levels (Rigat *et al.*, 1990). The deletion-allele has been proposed as a renal and cardiovascular risk factor (Staessen *et al.*, 1997).

From Ang II to Ang-(1–7): ACE2

ACE2 is a close homolog of ACE discovered in 2000 by two independent molecular approaches (Tipnis *et al.*, 2000; Donoghue *et al.*, 2000). The ACE2 gene is located on chromosome Xp22, a locus that was already known to be linked to hypertension when ACE2 was discovered, which suggested that ACE2 could be a key gene contributing to this link. Gene deletion of ACE2 in mice revealed it to be an essential regulator of heart function counter-balancing ACE (Crackower *et al.*, 2002). Even partial (heterozygote) loss of ACE2 is sufficient to enhance the susceptibility to heart disease (Wang *et al.*, 2014). ACE and ACE2 are single span, transmembrane proteins with their N-terminal catalytic sites being exposed on the extracellular surface, facilitating the metabolism of circulating peptides. The ACE2 protein resembles a chimera composed of a single ACE-like catalytic ectodomain fused to a homolog of the small transmembrane protein, collectrin. Despite having high similarity in sequence to ACE, particularly around the active site, ACE2 acts as a carboxypeptidase removing just a single amino acid from the C-terminus of susceptible substrates (Tipnis *et al.*, 2000). The distinct binding specificity of ACE2 was demonstrated by the failure of ACE inhibitors to block its activity. Comparative substrate specificities of ACE and ACE2 for angiotensin and bradykinin peptides are shown in Figure 2. Like ACE, the

activities of ACE2 are chloride-dependent, which is due to the presence of a comparable CL1 site in the ectodomain as revealed by structural and modeling studies (Rushworth *et al.*, 2008).

Soon after the discovery of ACE2, potent and specific inhibitors were rationally developed, for example, the compound MLN-4760 (Dales *et al.*, 2002), which has been used in numerous studies of ACE2 action *in vivo* and *in vitro*. MLN-4760 is a non-peptide inhibitor with which the inhibitor-bound crystal structure was subsequently solved (Towler *et al.*, 2004). MLN-4760 (also known as GL1001) was originally, but unsuccessfully, developed as a potential antiobesity drug and more recently is being examined as an anti-inflammatory agent (Byrnes *et al.*, 2009). Several other selective and potent ACE2 inhibitors have been developed, including a peptide inhibitor, DX600, (Huang *et al.*, 2003) and, more recently, a phosphinic-peptide (416F2), which mimics the enzyme transition state (Mores *et al.*, 2008).

ACE and ACE2 appear to be co-regulated with ACE2 being down-regulated in hypertension an effect that is mediated, at least in part, by Ang II (Gallagher *et al.*, 2008) although the mechanism is unclear. Some other peptide and steroid hormones modulate ACE2 expression levels as well as hypoxia and action of some cytokines. ACE2, like ACE, appears to be regulated by AMP kinase activation through epigenetic control via the histone deacetylase, SIRT1 (Clarke *et al.*, 2014). At the posttranscriptional level, miRNAs are also reported to regulate ACE2 expression (miRNA-143 and 421) (Fernandes *et al.*, 2011; Lambert *et al.*, 2014). These various regulatory sites may provide opportunities for therapeutic modulation of ACE2 whose up-regulation appears to be cardioprotective. ACE2 is shed from the membrane through proteolytic cleavage by

Comparative substrate specificity of ACE and ACE2

	ACE	ACE2
Angiotensin I	Asp Arg Val Tyr Ile His Pro Phe ↑ His Leu	Asp Arg Val Tyr Ile His Pro Phe His ↑ Leu
Angiotensin II	Not cleaved	Asp Arg Val Tyr Ile His Pro ↑ Phe
Angiotensin-(1–9)	Asp Arg Val Tyr Ile His Pro ↑ Phe His	Not cleaved
Angiotensin-(1–7)	Asp Arg Val Tyr Ile ↑ His Pro	Not cleaved
Angiotensin A	Not cleaved	Ala Arg Val Tyr Ile His Pro ↑ Phe
Bradykinin	Arg Pro Pro Gly Phe Ser Pro ↑ Phe Arg	Not cleaved
(des-Arg ⁹) Bradykinin	Not cleaved	Arg Pro Pro Gly Phe Ser Pro ↑ Phe

Figure 2 Comparative substrate specificity of ACE and ACE2. The hydrolysis of angiotensin and bradykinin peptides by ACE and ACE2 is illustrated. ↑ indicates the site of enzyme cleavage (peptidyl dipeptidase action for ACE) and carboxypeptidase action for ACE2. The heptapeptide product of angiotensin A cleavage by ACE2 is alamandine (Lautner *et al.*, 2013).

ADAM17 and, like ACE, this process is regulated by calmodulin (Lambert *et al.*, 2008). Furthermore, it has been shown that Ang II induces ACE2 shedding by promoting ADAM17 activity through signaling by reactive oxygen species (Patel *et al.*, 2013). This creates a positive feedback mechanism whereby Ang II facilitates the loss of its negative regulator, ACE2. For more detail on the regulation of ACE2, see Clarke and Turner, 2012.

The Natriuretic Peptide Family and Their Proteases (Corin, Furin, and NEP)

The family of natriuretic peptides is an evolutionarily, highly conserved cardiac endocrine system that regulates salt and body fluid balance, and hence blood pressure. The natriuretic peptide system can be viewed as a counterbalance to the RAS. Originally discovered in the early 1980s (de Bold *et al.*, 1981), the natriuretic peptides are stored in and secreted from granules within atrial tissue cardiocyte cells. This group of peptides comprises three closely related members: atrial natriuretic peptide (ANP), brain or B-type natriuretic peptide (BNP), both mainly synthesized in the heart, and C-type natriuretic peptide (CNP) which has a much broader tissue distribution and is principally of endothelial cell origin. They are synthesized as large prepropeptides which are consecutively processed proteolytically by signal peptidase to form the inactive propeptide and then by a proprotein convertase to form the active peptide. The active, vasodilatory ANP is a 28-amino acid peptide containing a 17-amino acid disulfide-bridged ring structure which typifies this family and which is shared by BNP and CNP. In the case of ANP and partly for BNP, the proprotein convertase is a transmembrane, cardiac serine protease known as corin, which has substrate specificity similar to trypsin, cleaving at a basic amino acid. BNP can also be processed by the intracellular, Golgi-enriched serine protease, furin, and CNP is exclusively processed by this enzyme (Wu *et al.*, 2009).

The natriuretic peptides act through natriuretic peptide receptors NPR-A (both ANP and BNP) and NPR-B (CNP), both of which are linked to guanylate cyclase. A third receptor (NPR-C) was originally thought to act as a clearance receptor to remove the peptides but is now known to act through inhibition of adenylate cyclase and phospholipase C activation (Mouawad *et al.*, 2004). Knockout mice lacking ANP, NPR-A, or corin all display a hypertensive phenotype and, while BNP-null mice are not hypertensive, they display cardiac fibrosis showing BNP to act as a local regulator of ventricular remodeling. More recent data also imply that CNP and NPR-B can play important roles in regulating cardiac hypertrophy and remodeling (Del Ry, 2013).

Modulating natriuretic peptide levels can provide therapeutic opportunities in hypertension and heart failure and the discovery that the zinc peptidase NEP is the principal protease inactivating them (Kenny *et al.*, 1993) led to a profusion of activity into developing NEP inhibitors as potential antihypertensives, and even dual 'vasopeptidase inhibitors' inhibiting both ACE and NEP (Worthley *et al.*, 2004). However, the discovery that NEP inactivates the Alzheimer's disease-related and neurotoxic amyloid β -peptide (A β) (Iwata *et al.*, 2000) has diminished enthusiasm for such

developments since such inhibitors might potentiate the cognitive and behavioral problems associated with the disease. Potentiating other features of the natriuretic peptide systems may still provide novel therapeutics and the peptides and their precursor forms can also serve as valuable biomarkers of heart disease. These peptide systems have also been suggested to play a more general integrating role in lifestyle-related metabolic and cardiovascular disorders (Zois *et al.*, 2014).

The Endothelin Peptide Family and Their Proteases

A highly potent vasoconstrictor peptide produced and secreted by endothelial cells, endothelin-1 (ET-1), was first isolated and characterized in 1988 (Yanagisawa *et al.*, 1988) and shown to be synthesized from its large precursor, proET-1, through two successive proteolytic steps, firstly catalyzed by the proprotein convertase furin to form the inactive big ET-1 and then by a protease shown to be inhibited by the NEP inhibitor, phosphoramidon. However, the biosynthetic enzyme turned out not to be NEP itself but a subsequently cloned close homolog, now termed endothelin-converting enzyme-1 (ECE-1) (Xu *et al.*, 1994). Rather, NEP turned out to be the primary protease inactivating ET-1 (Vijayaraghavan *et al.*, 1990). This provides another evolutionary example in which two homologous proteases function successively to synthesize a vasoactive peptide hormone and to metabolize it (cf. ACE and ACE2 above). In total there are three endothelin peptides (ET-1, -2, and -3) synthesized from separate genes, although ET-1 is the most abundant in the vasculature. ET-1 is a 21-amino acid peptide consisting of two rings formed by two intra-chain disulfide bonds and a 6-residue C-terminal tail and the other ETs have similar structures. The ETs act through related receptor subtypes (ET-A and -B) and ET-1 receptor antagonists (e.g., bosentan) are licensed for use in pulmonary arterial hypertension. ECE-1 exhibits similar topology to NEP being a zinc metallopeptidase composed of a large extracellular or luminal C-terminal catalytic domain, a transmembrane region and a small N-terminal cytoplasmic domain. It exists in four isoforms (designated ECE-1a, b, c, and d), differing only in part of their N-terminal cytoplasmic domains, which are derived from a single gene through the action of alternative promoters. They have similar catalytic properties but distinct subcellular localization and tissue distribution (Turner *et al.*, 1998). A second ECE-like gene encodes an ECE-2 protein, which is mainly neuronally located and likely involved in endosomal processing of neuropeptide precursors. ECE-1 inhibitors have been developed and may have therapeutic applications in hypertension, chronic heart or renal failure, and cerebral vasospasm (Jeng *et al.*, 2002). However, their clinical use is somewhat compromised by the involvement of ECE-1 (and ECE-2), like NEP, in metabolism of the Alzheimer's amyloid β -peptide (Eckman *et al.*, 2001).

Summary

In summary, the complex biology of blood pressure regulation relies on the counter-balancing effects of a host of proteases mediating interconversions of several distinct peptide families

(angiotensins, bradykinin, vasopressin, natriuretic, and endothelin peptides). Several of these proteases are the targets for successful antihypertensive and cardioprotective drugs, as are the peptide receptors. Newer discoveries in the biology of blood pressure regulation (ACE2, mas receptor, Ang-(1-7), and other peptides) highlight novel opportunities for intervention and treatment of cardiovascular disease.

Cancer – Proteases in the Progression and Metastasis

K Ji and BF Sloane, Wayne State University School of Medicine, Detroit, MI, USA

Introduction

In 1946 Fischer proposed that tumor-associated proteolytic activity could be responsible for the degradation of extracellular matrix (ECM) and the subsequent invasion of the tumor into surrounding normal tissue (Fischer, 1946). Indeed proteases have been confirmed to play pro-tumor roles throughout malignant progression, starting with carcinogenesis (Edwards *et al.*, 2008; Mason and Joyce, 2011; Sloane *et al.*, 2013); however, some proteases are protective and antitumor (Lopez-Otin and Matrisian, 2007; Edwards *et al.*, 2008; Mason and Joyce, 2011; Sloane *et al.*, 2013). Interestingly, what we refer to as tumor proteases often are derived from stromal or immune cells that have infiltrated into the tumor rather than from the tumor cells (Edwards *et al.*, 2008; Mason and Joyce, 2011; Sloane *et al.*, 2013), thus broadening the challenge of targeting tumor proteases. The connectivity among the many proteases causally linked to malignant progression and what are the critical substrates cleaved by those proteases *in vivo* are not yet well understood (Doucet *et al.*, 2008; Doucet and Overall, 2008; Rodriguez *et al.*, 2010; Fortelny *et al.*, 2014). Substrates are not simply ECM proteins, but include numerous other proteins, for example, growth factors such as hepatocyte growth factor (HGF) (Lee *et al.*, 2000) and vascular endothelial growth factor (Lee *et al.*, 2005), adhesion molecules such as E-cadherin (David and Rajasekaran, 2012) and tenascin C (Mai *et al.*, 2002), other proteases (Edwards *et al.*, 2008; Mason and Joyce, 2011; Sloane *et al.*, 2013), signaling molecules (Lopez-Otin and Hunter, 2010), and endogenous protease inhibitors (Declercq *et al.*, 1997; Mason and Joyce, 2011; Laurent-Matha *et al.*, 2012), i.e., substrates that are activated or inhibited by limited proteolysis. In this chapter, we will briefly review data on the links between cancer progression and metastasis and a few selected proteases from the following five proteolytic clans: aspartic, cysteine, metallo, serine, and threonine (for further information see the MEROPS database: Rawlings *et al.*, 2014).

Aspartic Proteases

Cathepsin D

Cathepsin D, a lysosomal aspartic protease that is secreted by tumor cells, cleaves structural and functional proteins and peptides; inactivates chemokines such as macrophage inflammatory protein-1 alpha (Chemokine (C-C motif) ligand (CCL) 3), CCL4 and CCL21 (Wolf *et al.*, 2003); and cleaves prolactin (Piwnicka *et al.*, 2004) and osteopontin (Christensen *et al.*, 2010), thereby modulating their functions. Cathepsin D also enhances cysteine cathepsin activity in tumors by inactivating their endogenous inhibitor cystatin C (Laurent-Matha *et al.*, 2012). Cathepsin D, which is highly expressed in human breast carcinomas, is an independent marker of poor

prognosis (Foekens *et al.*, 1999; Fitzgibbons *et al.*, 2000; Rochefort *et al.*, 2000). Increases in levels and the secretion of cathepsin D are linked to size, grade, aggressiveness, metastasis and prognosis of endometrial, ovarian and breast cancers (Garcia *et al.*, 1996; Cunat *et al.*, 2004; Ioachin, 2005; Liaudet-Coopman *et al.*, 2006). All of these may be due to the stimulation of tumor cell proliferation by cathepsin D (Garcia *et al.*, 1990; Liaudet *et al.*, 1994, 1995; Glondou *et al.*, 2001), an effect that is not mediated by its proteolytic activity, but may be mediated by binding to yet unidentified cell surface receptors (Glondou *et al.*, 2001; Masson *et al.*, 2010). Thus, targeting the proteolytic activity of cathepsin D would not totally abrogate its pro-tumorigenic functions.

Cysteine Proteases

Calpains

Calpains are a family of intracellular calcium-dependent cysteine proteases, which cleave a broad spectrum of substrates including the cytoskeletal proteins talin, vinculin and desmin; membrane proteins (growth factor receptors, adhesion molecules, ion transporters); transcription factors (p53, c-fos); and enzymes (caspases, protein kinase C, RhoA/Rac) (Goll *et al.*, 2003; Anagli *et al.*, 2013). Calpains are involved in cancer-related processes such as cell motility, apoptosis and cell cycle regulation (Carafoli and Molinari, 1998; Ono *et al.*, 1998; Zatz and Starling, 2005). Increased expression of calpain 1 has been observed in schwannomas and meningiomas (Kimura *et al.*, 1998), renal cell carcinomas (Braun *et al.*, 1999) and breast carcinomas (Shiba *et al.*, 1996); calpain 2 in colorectal carcinomas (Lakshmikuttyamma *et al.*, 2004) and prostate carcinomas (Rios-Doria *et al.*, 2003); and calpain 6 in uterine sarcomas and carcinosarcomas (Lee *et al.*, 2007) and cervical cancers (Lee *et al.*, 2008). In contrast, calpain 9 is decreased in gastric cancer (Yoshikawa *et al.*, 2000). This altered expression of calpain family members in tumors would be consistent with a role for these enzymes in tumor progression (Storr *et al.*, 2011).

Caspases

One of the best-known proteolytic pathways is apoptosis in which caspases initiate and execute programmed cell death (Flutsch and Grutter, 2013). Indeed caspases are classified as either initiator caspases (caspase-2, -8, -9, and -10) or executioner caspases (caspase-3, -6, and -7). Once activated by initiator caspases, executioner caspases cleave a broad spectrum of cellular proteins, ultimately resulting to cell death (Nicholson, 1999). Failure of apoptosis could allow the survival of transformed cells; indeed, experimental evidence from transgenic mice and human cell lines shows that caspases-2, -3, and -8 act as tumor suppressors in colorectal, gastric, breast,

and lung cancers (Jager and Zwacka, 2010; Olsson and Zhivotovsky, 2011; Puccini *et al.*, 2013). Mutations of caspases-3 and -6 are observed in human gastric, colorectal and non-small cell lung cancers and multiple myeloma (Soung *et al.*, 2004; Lee *et al.*, 2006). In addition, gene polymorphisms for caspase-3, -7, -8, and -9 that alter caspase activity are associated with risks for lung (Son *et al.*, 2006; Lee *et al.*, 2010) and breast cancers (Theodoropoulos *et al.*, 2012). Thus, genetic alterations that disrupt caspase activity appear to enhance cancer development:

Cysteine Cathepsins

The human cysteine cathepsin family is comprised of 11 members: cathepsins B, C, F, H, K, L, O, S, V, W, X/Z (Mohamed and Sloane, 2006). They are often secreted from tumor cells and may associate with binding partners on the cell surface (Mohamed and Sloane, 2006; Victor and Sloane, 2007). Causal roles for lysosomal cysteine cathepsins in human and murine cancers are well documented; however, there is a need to define the critical substrates cleaved (Mohamed and Sloane, 2006; Gocheva and Joyce, 2007; Victor and Sloane, 2007; Turk *et al.*, 2012). There is functional redundancy and cooperativity among the cysteine cathepsins. For example, redundancy has been observed for cathepsins B and X: ablation of cathepsin B in breast tumor cells that express this enzyme on their surface is compensated for by a relocalization of cathepsin X to the cell surface with either of the two cysteine cathepsins supporting invasion of the breast tumor cells (Vasiljeva *et al.*, 2006). Cooperativity in breast cancer progression and metastasis has been shown for cathepsins B and X/Z in a cell type known to contribute to malignant progression, i.e., carcinoma-associated fibroblasts (Orimo and Weinberg, 2006; Shimoda *et al.*, 2010). Ablation of both enzymes increases secretion of matrix metalloproteinase (MMP)-2, N-cadherin and neural cell adhesion molecule and decreases secretion of periostin by fibroblasts, changes that are consistent with the two enzymes playing causal and cooperative roles in cell adhesion and ECM remodeling. Individual ablation of cathepsin B or L has a more limited impact on the fibroblast secretome (Tholen *et al.*, 2014). Cysteine cathepsins exhibit cooperation with other proteases as well. For example, cathepsin B can trigger the plasminogen activation cascade (Kobayashi *et al.*, 1991; Guo *et al.*, 2002) and activate MMP2 and 9 in tumor-shed microvesicles or exosomes (Giusti *et al.*, 2008). Most cysteine cathepsins require acidic pH for optimal activity, raising a question as to their roles pericellularly; however, solid tumors acidify their microenvironment and cysteine cathepsins have been demonstrated to degrade ECM surrounding tumors *in vitro* and *in vivo* (Robey *et al.*, 2009; Estrella *et al.*, 2013; Rothberg *et al.*, 2013). The activation of MMP2 and 9 in tumor exosomes by cathepsin B also is increased at acidic pH (Giusti *et al.*, 2008).

Elevated expression and activity of cysteine cathepsins have been shown to be associated with cancer progression in a wide variety of tumors (Jedezsko and Sloane, 2004; Mohamed and Sloane, 2006). In transgenic mouse models, multiple cysteine cathepsins have been confirmed to play causal roles in malignant progression of pancreatic islet cell and mammary tumors (Joyce *et al.*, 2004; Reinheckel *et al.*, 2012; Withana

et al., 2012) and cysteine cathepsin inhibitors shown to reduce tumor growth, invasiveness, and metastasis (Reinheckel *et al.*, 2012; Withana *et al.*, 2012), either alone or in combination with chemotherapy (Bell-McGuinn *et al.*, 2007; Shree *et al.*, 2011; Withana *et al.*, 2012). There are examples of tissue specificity: cathepsin B enhances progression of pancreatic islet cell tumors, pancreatic ductal adenocarcinomas and mammary carcinomas (Joyce *et al.*, 2004; Vasiljeva *et al.*, 2006; Gopinathan *et al.*, 2012), but not squamous cell carcinomas (Ruffell *et al.*, 2013). In contrast, cathepsin C regulates squamous cell carcinogenesis, but not mammary carcinogenesis (Ruffell *et al.*, 2013). Cysteine cathepsins may also be protective, as shown by the ablation of cathepsin L resulting in promotion of squamous cell carcinogenesis (Dennemark *et al.*, 2010). ‘Tumor’ cysteine cathepsins that contribute to malignant progression may come from tumor cells, infiltrating immune cells such as macrophages, infiltrating fibroblasts and/or endothelial cells (Vasiljeva *et al.*, 2006; Gounaris *et al.*, 2008; Joyce and Pollard, 2009; Herroon *et al.*, 2013; Small *et al.*, 2013). Since cysteine cathepsins from either tumor cells or other cells in the tumor microenvironment can modulate malignant progression, this increases the difficulty of targeting these enzymes in cancer.

Metalloproteases

ADAM and AMAMTS Proteases

The metalloproteases known as a disintegrin and metalloproteinase (ADAM) and ADAM with thrombospondin motifs (ADAMTS) are named after their domains: A Disintegrin And Metalloprotease and ADAM with ThromboSpondin motifs. The 21 human ADAM proteases are transmembrane and secreted proteins and have both an adhesion domain and a protease domain (Wolfsberg *et al.*, 1995; Przemyslaw *et al.*, 2013). In contrast, the 19 human ADAMTS proteases have in addition multiple thrombospondin 1-like repeats and are secreted proteins (Tang, 2001; Przemyslaw *et al.*, 2013). Dysregulated expression of ADAMs and ADAMTSs has been reported in a wide range of human cancers, where they are implicated as regulators of cancer progression that function in ECM remodeling, shedding of adhesion molecules and regulation of activity of growth factors, integrins and cytokines (Rocks *et al.*, 2008; Mentlein *et al.*, 2012; Przemyslaw *et al.*, 2013). Their functions include the shedding of tumor necrosis factor (TNF)- α by ADAM17 that is associated with the invasiveness of triple negative breast cancers (Giricz *et al.*, 2013) and the shedding of epidermal growth factor receptor (EGFR) ligands by ADAM17 in breast cancer (Kenny and Bissell, 2007). ADAM17 (Merchant *et al.*, 2008) and ADAMTS1 (Lind *et al.*, 2006), which is epigenetically deregulated, are implicated in colon cancer.

Antitumor roles for ADAMs/ADAMTSs are also observed: ADAMTS15 is genetically inactivated in colon tumor cells (Viloria *et al.*, 2009) and ADAMTS12 epigenetically silenced in colon tumor cells and transcriptionally activated in carcinoma-associated fibroblasts (Moncada-Pazos *et al.*, 2009), which is linked to an anti-proliferative effect on the colon tumor cells. ADAMTS1 and 18 exhibit anti-angiogenic and anti-metastatic

properties in several cancer types including breast and pancreatic cancer (Masui *et al.*, 2001; Porter *et al.*, 2004). ADAM28 has been proposed to be an oncogene in asbestos-related lung cancers (Wright *et al.*, 2010) and high expression of active ADAM28 has been observed in non-small cell lung carcinomas that metastasize to lymph nodes (Ohtsuka *et al.*, 2006). Cooperativity with other proteases may be required: MMP7 has been shown to activate ADAM28 (Mochizuki *et al.*, 2004). There are ongoing clinical trials with selective ADAM inhibitors in breast cancer (Duffy *et al.*, 2011), but such small molecule inhibitors are selective rather than specific and thus anticipated to have off-target effects (Coussens *et al.*, 2002) for discussion of problems encountered in use of broad-spectrum MMP inhibitors). Murphy and colleagues (Murphy, 2010; Richards *et al.*, 2012) are testing an alternative approach to inhibition of ADAM17 using blocking antibodies. Although the antibodies are specific, compensation by other proteases is observed when these are used *in vivo*, once again indicating the difficulty of targeting proteases therapeutically. More extensive discussions of ADAMs and ADAMTSs in cancer can be found in the following reviews (Murphy, 2008; Kataoka, 2009; Turner *et al.*, 2009; Klein and Bischoff, 2011; Wagstaff *et al.*, 2011; Kumar *et al.*, 2012; Grotzinger and Rose-John, 2013).

Matrix Metalloproteinases

The original link of MMPs to cancer came from studies that demonstrated their ability to degrade type IV collagen in the basement membrane (Liotta *et al.*, 1979, 1980). Indeed MMPs are often classified by their specificity for ECM substrates, for example, collagenases (MMP1, 8, 13) that degrade native fibrillar collagen; stromelysins (MMP3, 10, 11) that degrade proteoglycans and glycoproteins such as laminin and fibronectin; and gelatinases (MMP2, 9) that degrade type IV collagen and denatured fibrillar collagen. Nonetheless, MMPs cleave many other substrates that are critical to malignant progression, for example, growth factors, cytokines, receptors, protease inhibitors and adhesion molecules (Egeblad and Werb, 2002; Sloane *et al.*, 2013). Six of the 23 human MMPs are associated with the cell membrane: four are transmembrane and two are glycosylphosphatidylinositol (GPI)-anchored (Hernandez-Barrantes *et al.*, 2002; Sohail *et al.*, 2008). Expression of many MMPs is highly increased in human cancers and correlates with invasiveness, metastasis and poor prognosis (Coussens *et al.*, 2002; Egeblad and Werb, 2002). Causal roles in malignant progression have been established for a wide variety of MMPs by studies in which murine transgenic models for cancers are crossed into mice deficient in individual MMPs. Such studies have demonstrated causal roles at stages that span the spectrum from tumor initiation through metastasis. These pro-tumorigenic activities of MMPs have been recently reviewed in detail (Sloane *et al.*, 2013) and are also delineated in numerous review articles (see e.g., Seiki, 1999; Fillmore *et al.*, 2001; Edwards *et al.*, 2008; Sohail *et al.*, 2008; Kessenbrock *et al.*, 2010; Khokha and Werb, 2011; Sloane *et al.*, 2013). Pro-tumor activities depend not only on an individual MMP, but may depend on the cell that is expressing the MMP. This was shown for colon tumors using a model in which the mice are predisposed to develop intestinal adenomas; in these mice development of intestinal tumors is

linked to MMP7 in the tumor cells (Fingleton *et al.*, 1999) and to MMP9 in tumor-associated neutrophils (Sinnamon *et al.*, 2008), but not to MMP2, 12, or 19 expressed in either tumor cells or tumor-associated cells. Lung metastasis of murine mammary carcinomas has been linked to ablation of MMP9 in tumor-associated neutrophils, but whether this does or does not occur depends on the genetic background of the mice (Martin *et al.*, 2008). Thus, even the propensity of some MMPs to induce tumors and enhance progression is not straightforward, making therapeutic targeting of these enzymes difficult.

The literature reporting pro-tumorigenic roles for MMPs is extensive, yet some MMPs act as tumor suppressors (Lopez-Otin and Matrisian, 2007). Of the 24 murine MMPs, 10 have antitumor or anti-inflammatory properties (Dufour and Overall, 2013). Ablation of either MMP3 or MMP8 strongly increases skin tumorigenesis in mice (Balbin *et al.*, 2003; Mccawley *et al.*, 2004), an effect that in one study occurred in male mice, but not female mice, unless they were ovariectomized or treated with tamoxifen (Balbin *et al.*, 2003). MMP8 inactivates pro-inflammatory cytokines and chemokines, a result that is consistent with the MMPs that are protective being expressed primarily in inflammatory cells associated with the skin tumors. Loss-of-function mutations that abrogate MMP8 activity have been found in human melanomas where they are associated with enhanced progression (Lopez-Otin *et al.*, 2009), whereas increases in MMP8 expression in human breast and oral carcinomas are associated with better prognosis (Lopez-Otin *et al.*, 2009). MMP3, as referenced above, can be antitumor in the skin, yet also can be pro-tumor as in murine mammary carcinomas and pancreatic ductal adenocarcinomas where it plays a role in tumor initiation (Sternlicht *et al.*, 1999; Lopez-Otin *et al.*, 2009). MMP3 also has been shown to be protective (Witty *et al.*, 1995), in this case in another mouse mammary carcinoma that is chemically-induced. Other MMPs shown to have dual roles in cancer are MMP9, 11, and 19 (Lopez-Otin and Matrisian, 2007). These findings indicate the complexities of targeting MMPs in cancer progression and metastasis and may account in part for the failure of broad-spectrum MMP inhibitors in clinical trials (Coussens *et al.*, 2002) and indicate the need to design inhibitors so that they do not target MMPs that have antitumor and anti-inflammatory roles (Dufour and Overall, 2013).

MMPs like cysteine cathepsins (see above) and serine proteases (see below) exhibit redundancy and cooperativity. Ablation of individual MMP genes, with the exception of MMP14 or MT1-MMP (Holmbeck *et al.*, 1999), does not result in an overt phenotype, findings consistent with there being functional redundancy among these enzymes (Page-Mccaw *et al.*, 2007). Proteases other than MMPs have been found to compensate when there is a deficiency in an MMP. For example, a surprising finding is that two mouse models of pancreatic neuroendocrine carcinomas become more invasive when MMP9 is ablated. This was shown to be due to an increase in the cysteine protease cathepsin B as a result of infiltration of a cathepsin B-expressing subpopulation of inflammatory cells at the invasive front of the tumors (Shchors *et al.*, 2013). Proteases of different clans, in this case MT1-MMP and the cysteine protease cathepsin K, cooperate to

promote invasion through collagen I by breast cancer cells (Montgomery *et al.*, 2012). This is not surprising given that these two enzymes have been shown to function in mesenchymal cells and macrophages in complementary pathways of collagen I degradation (Madsen *et al.*, 2007; Madsen and Bugge, 2013; Fonovic and Turk, 2014). However, it does not agree with the contention by Weiss and colleagues that only MT1-MMP is required for collagen I invasion by human mesenchymal stem cells (Lu *et al.*, 2010) and for the focal collagenolysis that supports the invasive phenotype of cancer cells (Sabeh *et al.*, 2009). These disparate results may reflect differences in the conformation of the collagen matrices used by investigators in *in vitro* analyses of collagen degradation as proposed by Weiss and colleagues; however, the two complementary pathways are observed *in vivo*. Yet another intriguing cooperativity has been observed among MMPs (MMP3, 10, and 13) in regard to degradation of collagen, in this case in a rat mammary carcinoma cell line. This cooperativity involves crosstalk between cells that retain epithelial characteristics and ones that have undergone an epithelial-mesenchymal transition (Martorana *et al.*, 1998). To understand the roles of MMPs in malignant progression, we will need to define the *in vivo* substrates that are critical to progression and the cellular sources of the MMPs that degrade those substrates as well as pathways for cooperativity with other MMPs or with proteases of other clans (see also Concluding Remarks).

Serine Proteases

There are 176 putative serine proteases (Puente *et al.*, 2003) in the human genome, a large majority of which have been implicated in cancer (see Netzel-Arnett *et al.*, 2003; Emami and Diamandis, 2008; Oikonomopoulou *et al.*, 2010; Webb *et al.*, 2011; Batra *et al.*, 2012; Liu *et al.*, 2012 for reviews). Due to space limitations, we will limit our review of serine proteases in cancer to the plasminogen activation system and one of the transmembrane serine proteases matriptase, which has oncogenic activity (see also Sloane *et al.*, 2013 for a more detailed discussion).

Plasminogen Activation System

The plasminogen activation system has been demonstrated to play a causal role in virtually all cancers (Dano *et al.*, 2005), including in their metastasis (Sidenius and Blasi, 2003; Dano *et al.*, 2005; Sloane *et al.*, 2013). The penultimate protease is plasmin, which is generated from plasminogen by one of two plasminogen activators: tissue plasminogen activator or urokinase plasminogen activator (uPA). The latter has been implicated in cancer and is often considered to be a therapeutic target that is preferable to plasmin (Hildenbrand *et al.*, 2010). uPA is itself a serine protease, associates with the cell surface by binding to the GPI-anchored receptor urokinase plasminogen activator receptor (uPAR), is inhibited by the plasminogen activator inhibitors-1 (PAI-1) or PAI-2 and is activated from pro-uPA by plasmin (Bekes *et al.*, 2011) via a feedback loop or other proteases such as the cysteine protease cathepsin B (Guo *et al.*, 2002). Bound uPA activates plasminogen more

efficiently than soluble uPA and focuses the proteolytic activity of plasmin to regions adjacent to the tumor cell surface. Plasmin has a broad substrate specificity and can degrade ECM proteins such as laminin and fibronectin directly (Andreasen *et al.*, 1997) as well as indirectly by activating MMP3, 9, 12, and 13 (Carmeliet *et al.*, 1997; Mason and Joyce, 2011). The various components of the plasminogen activation system are not necessarily expressed by tumor cells; stromal cells are for example the source of uPA in colon tumors and in addition which cells are the source of the various components of this system differs from one type of tumor to another (Dano *et al.*, 2005).

Studies in which mice deficient in plasminogen activation system components are crossed with transgenic models for cancer, reviewed in (Sloane *et al.*, 2013), have confirmed roles for uPA and plasminogen in invasion and metastasis of mammary carcinomas, but not in growth of the primary tumors; furthermore, neither uPAR or PAI-1 deficiency was found to have an effect. In contrast, ablation of uPA did not affect pancreatic islet cell tumorigenesis or the angiogenic switch that accompanies progression of these tumors. Ablation of PAI-1 does not affect skin carcinogenesis, but on the other hand inhibition of PAI-1 by small molecule inhibitors suppresses intestinal tumorigenesis (Hildenbrand *et al.*, 2010), indicating differences from one tumor type to another. The apparent lack of effects in regard to angiogenesis are somewhat surprising given the key roles established for the plasminogen activation system in the neoangiogenesis that is associated with prostate carcinoma cells *in vivo* (Conn *et al.*, 2009). Quigley and colleagues have suggested that the most effective therapeutic approach would be to target activation of pro-uPA at the apex of the plasminogen cascade through use of activation blocking antibodies rather than through use of protease inhibitors (Bekes *et al.*, 2011). In a recent review they discuss whether plasmin exerts its pro-tumor effects primarily through cleavage of cell surface proteins rather than ECM remodeling and ways that these cell surface proteins might be targeted to prevent cleavage and thereby reduce metastasis (Deryugina and Quigley, 2012). Thus, despite the extensive literature on the plasminogen activation system in cancer, reagents that will successfully target this system remain elusive.

Type II Transmembrane Trypsin-like Serine Proteases: Matriptase

Proteases of the TTSP family have been implicated in cancer initiation and progression (Sloane *et al.*, 2013). There are 17 human TTSPs (Netzel-Arnett *et al.*, 2003). The member that has been most studied is matriptase (also known as MT-SP1, TADG-15, epithin, and ST14), which was originally defined as a secreted gelatinase (Shi *et al.*, 1993). Matriptase is expressed in epithelial cells in breast, skin, prostate, ovary, stomach, and lung (Kim *et al.*, 1999; Takeuchi *et al.*, 1999; Oberst *et al.*, 2001; Tanimoto *et al.*, 2001) and plays a key role in the formation and maintenance of epithelial integrity (Carney *et al.*, 2007; List *et al.*, 2009). Substrates cleaved by matriptase include HGF, uPA (Lee *et al.*, 2000), MMP3 (Jin *et al.*, 2006), protease-activated receptor-2 (Takeuchi *et al.*, 2000), prostasin, macrophage stimulating protein-1, epithelial sodium channels (Andreasen *et al.*, 2006), acid-sensing ion

channel-1 (Clark *et al.*, 2010), fibronectin, and laminin (Satomi *et al.*, 2001), accounting for the role of this enzyme in cell growth, motility, survival, ECM remodeling, and skin barrier function under both physiological and pathological conditions.

A causal role for matriptase in initiation and progression of cancer has been demonstrated using a transgenic mouse model in which overexpression of matriptase is targeted to the skin. These mice develop spontaneous squamous cell carcinomas, consistent with an oncogenic function for matriptase, and are susceptible to carcinogen-induced tumor formation (List *et al.*, 2005). This oncogenic activity of matriptase can be abrogated by engineering expression of the cognate matriptase inhibitor, hepatocyte growth factor activator inhibitor (HAI)-1 in the basal layer of the mouse skin (List *et al.*, 2005). Matriptase can contribute to metastasis of gastric cancer cells: cells that have been engineered to express high levels of active matriptase exhibit an increase in metastasis to the lymph nodes (Ihara *et al.*, 2002). The pro-oncogenic and pro-metastatic activity of matriptase is proposed to be due to its activation of pathways linked to malignant progression, for example, HGF (Szabo *et al.*, 2011) and uPA (Ried *et al.*, 1999; Moriyama *et al.*, 1999; Lee *et al.*, 2000; Suzuki *et al.*, 2004). Indeed, c-Met-induced squamous cell carcinogenesis is initiated by matriptase (Szabo *et al.*, 2011). There is an exquisite balance between matriptase and HAI-1 that correlates with the grade of malignancy and is predictive of survival in human cancers including breast, cervical, ovarian, pancreatic, and prostate (Oberst *et al.*, 2002; Kang *et al.*, 2003; Uhland, 2006; List, 2009). In some tissues, matriptase appears to have an antitumor effect as downregulation of both matriptase and HAI-1 has been reported in gastrointestinal cancer (Zeng *et al.*, 2005). Targeting matriptase or downstream signaling pathways is being pursued, yet the possible antitumor effects in some tissues indicate a need to further define these pathways.

Threonine Proteases

Proteasomes

Proteasomes are multi-catalytic protease complexes engaged in recycling of intracellular proteins of short life span. These protein degradation machines play a role in elimination of cellular proteins that have been tagged for degradation through a complex modification termed polyubiquitination. More than 80% of cellular proteins are degraded through this pathway including those involved in an array of processes such as cell cycle, apoptosis, transcription, DNA repair, protein quality control, and antigen presentation (Dahlmann, 2007; Demasi and Laurindo, 2012). The 26S proteasome consists of a 20S proteolytic and a 19S regulatory subunit; there are three catalytic activities in the 20S subunit: caspase-like, trypsin-like, and chymotrypsin-like. The ubiquitin-proteasome pathway regulates signal transduction pathways that contribute to initiation and progression of cancer (Fuchs, 2002); thus, targeting the ubiquitin-proteasome pathway would appear to be a potential anti-cancer strategy. For more detailed information on the association of proteasomes with cancer and the potential of targeting proteasomes for cancer chemotherapy (please see Almond and Cohen, 2002; Sloane *et al.*, 2013).

Bortezomib, dipeptide boronic acid, was the first synthetic proteasome inhibitor (Adams *et al.*, 1998) and is approved by

the FDA for the treatment of multiple myeloma, pancreatic, and thyroid cancer (Kane *et al.*, 2003; Nawrocki *et al.*, 2005; Wunderlich *et al.*, 2012). Bortezomib targets the chymotryptic activity of the 20S proteasome. More recently compounds such as Carfilzomib (PR-171), Salinosporamide A (NP-0052), and MLN9708 have shown promising results in clinical trials (Chari *et al.*, 2010; Demo *et al.*, 2007). Moreover, many such compounds are also being tested in preclinical studies on cancer cell lines (Milacic *et al.*, 2008; Piva *et al.*, 2008; Yang *et al.*, 2009; Dai *et al.*, 2010). These proteasome inhibitors inhibit cell proliferation, induce cell cycle arrest, autophagy, and apoptosis.

One of the well-known functions of the proteasome is regulation of the transcription factor nuclear factor kappa B (NF κ B). NF κ B regulates a variety of inflammatory responses, including activation of pro-inflammatory cytokines that promote tumorigenesis (Cortes Sempere *et al.*, 2008; Grivennikov and Karin, 2010; Ben-Neriah and Karin, 2011). Inhibition of the proteasome by bortezomib induces accumulation of the inhibitor of NF κ B (I κ B), resulting in downregulation of transcriptional targets of NF κ B. However, in endometrial carcinoma cells and primary explants proteasome inhibitors activate NF κ B instead of blocking its transcription (Dolcet *et al.*, 2006). In multiple myeloma cells, bortezomib has been shown to activate NF κ B by triggering two upstream NF κ B activating kinases (I κ B kinase beta and receptor-interacting protein 2) in multiple myeloma cells (Hideshima *et al.*, 2009). These conflicting results may result in off-target effects of proteasome inhibitors like bortezomib and may contribute to development of resistance to proteasome inhibitors. Nonetheless the proteasome remains a viable target for cancer therapy and proteasome inhibitors an important example of protease inhibitors that have shown efficacy in the clinic.

Concluding Remarks

There is considerable evidence that proteases play critical roles in cancer progression, targeting a diversity of substrates and participating in steps from tumor initiation to metastasis. Here we have selected a few proteases for discussion and tried to indicate the connectivity between proteases of a single clan as well as between proteases of multiple clans. There are data on substrate specificity for many of the human proteases, but these data are for the most part from *in vitro* analyses, often carried out under conditions that would not be encountered by proteases secreted from tumor cells or associated with the tumor cell surface such as hypoxia and acidosis (Estrella *et al.*, 2013; Rothberg *et al.*, 2013). Thus there is clearly a need to identify the substrates cleaved by proteases *in vivo*. Some investigators have emphasized the importance of using protein substrates that are in their native conformation to the accurate identification of the proteases that cleave those substrates, for example, native type I collagen (Sabeh *et al.*, 2009). More than one protease is likely to cleave any given substrate and a deletion of one protease is likely to result in compensatory changes in other proteases that can cleave that substrate. Furthermore, proteases cleave more than one substrate, as is particularly true for the promiscuous lysosomal cysteine cathepsins.

Overall and colleagues (Fortelny *et al.*, 2014) have assembled curated and publically-available protease cleavage

and inhibition data from 4 of the 5 clans of proteases discussed here (aspartic, cysteine, metallo, and serine) into a computational representation that they term the protease web. This representation establishes that proteases do not act alone or in isolated hierarchical cascades such as the plasminogen activation cascade. Instead they operate in interactive networks that are multi-directional. Of note is that endogenous protease inhibitors are key components of the protease web and that a limited number of proteases form nodes in the web. This may reflect a larger literature on proteases that have been studied for years, rather than a critical role for those proteases. From the protease web, we can see that proteases can regulate the activity of proteases of a different clan; for example, metalloproteases were found to cleave serine proteases or their cognate inhibitors, the serpins. Other factors that need to be considered in regard to the protease web are temporal and dynamic changes that occur in protease expression and localization, changes that may influence the activation or inhibition of the proteases. These computational analyses are as of yet incomplete. Much of the information on substrates and inhibition was obtained in studies performed with purified proteases *in vitro* so there was a preselection of potential substrates rather than an unbiased global approach to substrate identification. Furthermore, the studies were based primarily on analysis of cleavage of single substrates rather than cleavage of a substrate in a milieu in which cleavage might be influenced by the presence of competing substrates. Cellular and subcellular sources of the proteases and inhibitors and how that might alter the connectivities observed also needs to be addressed. When targeting proteases therapeutically, we need to consider the protease web and how targeting one or a family of proteases may lead to unanticipated results. Nonetheless, proteases are viable therapeutic targets due to the alterations in their expression and localization that accompany tumor development and progression.

Introduction

Cell Biology of the Lysosome

Christian de Duve, who discovered the lysosome, understood its dynamic nature almost from the outset: its distinctive acid micro-environment represented a destination for membrane structures and other organelles actively recycled within the cell (De Duve and Wattiaux, 1966; Klionsky, 2007). The nature of the lysosome and its biogenesis are reviewed elsewhere in this encyclopedia. Ultrastructural studies – that followed the first (biochemical) exploration of the cell – revealed peroxisomes, mitochondria, and exogenous particulate material within unit membrane-bound spaces staining positively for acid phosphatase activity (Ashford and Porter, 1962). These findings indicated that the lysosome is not only specialized for and a principal site of intracellular digestion, but constitutes part of an intracellular network which engages with other organelles and is in contact with the plasmalemma and its invaginations (Geuze *et al.*, 1985).

Recycling of other organelles and membrane structures by means of autophagy, together with fluid-phase pinocytosis, and receptor-mediated uptake of proteins by endocytosis, shows that the lysosomal compartment is exposed continually to the external environment (De Duve, 1964). The medical realization of this concept, which represents a potential access route for treating diseases affecting the lysosome, has already borne fruit in stem-cell transplantation and targeted biological therapies; it can also be exploited in therapeutic gene transfer (Cachón-González *et al.*, 2012).

Debt of Cell Science to Medicine

The Nobel prize for Medicine and Physiology, awarded in CE 1974 jointly to de Duve, Claude, and Palade, was a critical landmark in the new science of cell biology. Insights into the physiological rôle of the lysosome have consistently accrued from studies of inborn errors which affect the organelle. Scientific understanding of the dynamic interactions of the living cell has latterly emerged from exploration of the biochemical genetics of lysosomal diseases aided by multimodal techniques in microscopy combined with sophisticated immunological methods for molecular identification. In short, the systematic characterization of disorders affecting the lysosome is a potent source of mechanistic information in that branch of physiology represented by contemporary molecular cell biology (Xu and Ren, 2015). The former concept of the lysosome as the constitutive recycling organ of the cell with a simple destructive rôle in organizing macromolecular catabolism is no longer tenable: in the last years intensive studies based on observations in lysosomal diseases have revealed a biochemically and physically dynamic organelle that is at the center of a reactive control network which regulates cell metabolism and subject to input from countless exogenous and internal signals.

The Lysosomal Compartment

A complement of $\approx 10^3$ lysosomes is present in nearly all mammalian cells but notably absent in mature red blood cells. When the function of this organelle is defective, the range of manifestations is extreme but varies according to the particular lysosomal function which is disturbed and the extent to which the integrity of any given cell or tissue is dependent on that function. In the case of relative or absolute deficiency of lysosomal acid hydrolases (generally proteins found in the matrix of the unit-bound membrane space of the lysosome), manifestations of the genetic defect reflect the turnover rate of the macromolecular substrate(s) of the given enzyme system (Futerman and van Meer, 2004).

The lysosome and related membrane compartments of the cell, including the endosomal system, constitute an extensive network of functioning proteins continuously undergoing turnover and programmed interchanges at defined membrane-contact sites. These interchanges are subject to complex regulatory influences. After receptor-mediated endocytosis, endosomes form by internalization and fuse with early lysosomal vesicles as part of nutrient-gathering and transmission of signals initiated by ligand–receptor interactions. Simultaneously, the lysosomal compartment accepts the inflow of intracellular material – principally particulate or membranous – derived by autophagy. Breakdown products of the autophagosome and endolysosomal pathways are released for conservative resynthesis as part of the constitutive turnover of cellular components (Müller *et al.*, 2015). Dynamic recycling of polypeptides, glycosaminoglycans, and complex sphingolipids is accompanied by similar turnover of nucleic acids since the lysosome also harbors a complement of nucleases which participate in the turnover of mitochondrial, ribosomal, as well as exogenous polynucleotides. Lysosomes themselves are subject to active turnover as a result of fusion and rapid pH changes occurring within the common lumen after vesicular exchange. The membrane of the lysosome contains numerous highly glycosylated proteins forming an internal glycocalyx including integral lysosomal proteins (LIMPS) and the lysosomal-associated membrane proteins (LAMPs) (Safitig and Klumperman, 2009). Maintenance of a proton gradient with a concentration of protons ≈ 1000 -fold greater than that in the ambient cytosolic pH, depends on the presence of a vacuolar, (V-type) H^+ ATPase in the lysosomal membrane (Mindell, 2012). Other membrane transporters exist for the counter-exchange of ions, including the chloride channel, CLCN7 – mutations in which are responsible for dominantly inherited and severe autosomal recessive forms of osteopetrosis – in a recessive variant, severe neurodegeneration occurs. The CLCN7 channel is expressed in the endosome–lysosomal membranes of all cells but is also abundant on the ruffled border of the osteoclast. Other channels include those that transport Ca^{2+} (LAAT1), as well as the egress of small molecules generated by hydrolytic digestion of the macromolecular substrates in the

lysosome – for example, cystinosis (cystine), Cbl F (cobalamin), and sialin (sialic acid). Mutations in each of these are responsible for cognate lysosomal diseases.

Lysosomes acquire complex macromolecules for recycling and breakdown by (1) receptor-mediated endocytosis; (2) engulfment and fusion, for example in phagocytosis; and (3) autophagy – a variant of which, crinophagy, is involved in the maintenance of the contents of secretory granules, which if not discharged, are fused with lysosomes for reclamation of their contents. Latterly numerous molecular components which bring about trafficking and membrane-fusion events, for example Rab proteins and SNARE proteins, are localized to, and interact with the organelle – thus participating in the ebb-and-flow of substrates and digestive products as they move between compartments in the greater lysosomal network in the cell.

Endocytosis

Internalization of ligands for receptors by endocytosis at the cell surface facilitates the delivery of nutrients and molecules released within the cell after endocytic fusion with lysosomes to form the ‘endolysosome.’ Loss of certain membrane components and intensified acidification leads ultimately to formation of the phagolysosome. The acquisition of cholesterol bound to apolipoprotein B in low-density lipoproteins from the plasma and of iron bound to plasma transferrin enable the cognate membrane receptors to be returned to the cell surface, having despatched their complex cargo (Kornfeld and Mellman, 1989). Some receptor complexes are not retrieved but are degraded after fusion with mature lysosomes, for example, epidermal growth factor receptors. While the mechanism by which lysosomal diseases disrupt endosomal activity is not fully worked out, some lysosomal diseases are associated with abnormalities of serum lipoproteins and iron status, which may reflect disturbed endocytosis of receptors, for example, transferrin receptors.

Antigen presentation

In antigen-presenting cells, cysteine proteinases (cathepsins) cleave endocytosed protein antigens to generate peptide fragments of the cognate antigens that are ultimately presented by major histocompatibility complex (MHC) class II molecules. This is an essential step for induction of the adaptive immune response. Deficiency or inhibition of lysosomal acid proteinases, particularly cathepsin S, has been shown experimentally to attenuate the development of autoimmunity (Baugh *et al.*, 2011). Enhanced autoimmunity or disturbance of the adaptive immune response occur in several lysosomal diseases in humans, and may be partly explained by the coordinate expression of several lysosomal proteinases, including the cathepsins; this phenomenon may reflect expansion of the lysosomal network and enhanced activity of transcription factor EB (TFEB).

Phagocytosis

Lysosomes participate in phagocytosis, a key function of the innate immune system responsible for the degradation of microbes, as well as the physiological turnover of effete blood cells. First noted by I.I. Metchnikoff in CE 1882 (Metchnikoff, 1884), and widely distributed in nature, phagocytosis leads to

engulfment of particulates including bacteria, yeasts, and colloidal suspensions; this requires active membrane-fusion events (the term ‘phagolysosomes’ was introduced by de Duve) and is a particular feature of macrophages and dendritic cells (Aderem and Underhill, 1999). This process also represents an orchestrated interaction between innate immunity and the adaptive responses related to antigen presentation.

Autophagy

Three distinct intracellular activities participate in autophagy: microautophagy, chaperone-mediated autophagy, and macroautophagy. The latter was first identified as a result of appearance of ingested mitochondria, peroxisomes, and other membranous material within acid phosphatase-enriched unit membrane-bound vesicular structures, and the first insights into autophagy by de Duve and colleagues led to the coining of the term early in a long path of discovery (De Duve and Wattiaux, 1966; Klionsky, 2007; Ashford and Porter, 1962; De Duve, 1964).

The physiological significance of autophagy was clarified when excess glycogen was identified in the lysosomal compartment of patients with acid maltase deficiency due to Pompe disease. Accumulation of internal cellular debris representing the engulfment of relatively large-volume material, including other organelles and membrane fragments, occurs in a dynamic process of flow and fusion – a key function of the lysosome now termed macroautophagy (this includes ‘mitophagy,’ which refers specifically to the engulfment of mitochondria) (Yang and Klionsky, 2010). Macroautophagy is not only critical for nutrient retrieval through recycling of molecular building blocks in periods of starvation and other metabolic stress – it plays a constitutive rôle in developmental remodeling and maintenance of integrated cell function in health.

Microautophagy describes a continuous constitutive process in which cytosolic components trapped during invagination of endosomes occurs: cytosolic molecules are engulfed by invagination of lysosomal or endosomal membranes.

In chaperone-mediated autophagy, cytosolic proteins enter lysosomes principally from the cell surface through chaperone- and receptor-mediated internalization. This is known, partially through the genetic characterization of Danon disease, to involve protein unfolding and translocation mediated by the lysosomal membrane protein isoform, LAMP2a.

Autophagy, now more definitively termed macroautophagy, has been conserved throughout eukaryotic evolution; it involves sequestration of a cytosolic region and its particulate contents. The cytosol is at first surrounded and then sealed off with the formation of a phagophore – a double-layer membrane vesicle designated for recycling. The formation of the phagophore is initiated when a planar membrane cisterna appears to cordon off small volumes of cytoplasm and their contents to form a double-layered space. Sequestered cell cargo enters a stepwise process of compositional maturation and ultimately fusion of the vesicular structure with vacuoles and lysosomes. Intensive genetic studies in baker’s yeast have revealed cellular machinery that requires the products of more than 30 genes, termed essential autophagy (Atg) genes which include those encoding ubiquitin-like conjugation systems. Organelles and other content

engulfed as cargo in the new vesicular spaces include endoplasmic reticulum, ribosomes, mitochondria, peroxisomes, as well as recognizable glycogen: all are ultimately distributed to form autophagosomes – first named by de Duve. Subsequent ordered maturation also involves fusion with endosomal and lysosomal vesicles.

The stepwise processes with which macroautophagy engages are tightly regulated; but the mechanisms that control fusion and subsequent maturation are not fully understood. The terms accorded to the component structures are (1) the autophagosome (or early autophagic vacuole); (2) the amphisome (late or degradative autophagic vacuole); and, after fusion with the lysosome; (3) the autolysosome. Ambiguities arise because in ultrastructural studies the term autophagic vacuole is generally preferred for structures (2) and (3) since the molecular components were difficult to define before the introduction of dynamic high-resolution imaging studies. The maturation process involves increasing membrane cholesterol content, progressive acidification, and other changes in molecular composition – in the latter stages these include acquisition of lysosomal membrane proteins (Saftig and Klumperman, 2009; Eskelinen, 2005).

While systematic studies in yeast mutants have greatly advanced this field, clarification of the rôle of many of the molecular components of macroautophagy in mammalian cells still awaits systematic investigation in a pathophysiological context. Most of the genes and their products so far identified affect the early steps in induction of phagophores or autophagosomes. Important signaling cascades that induce or suppress autophagy are now known, but the dynamic forces and interrelationships between the pathways that drive autophagy are ill-understood. Several intracellular membrane domains including the endoplasmic reticulum, Golgi organ, mitochondria, and plasmalemma may be the true source of autophagic membranes, but trafficking requires components of the secretory pathway, as well as the SNARE fusion machinery including *N*-ethylmaleimide-sensitive attachment protein (SNAP) receptor (SNARE) proteins. Rab GTPase-activating proteins (Rab GAPs) are implicated in the spatial and temporal dynamics of the cellular endomembrane system and reconstitution studies confirm the requirement for SNAREs28. RAB5 and RAB7 are specifically involved in the tethering and docking processes in endo-lysosomal membrane trafficking (Popovic *et al.*, 2012). Formation of phagophores in mammalian cells requires an often-studied protein, LC3 (microtubule-associated protein 1 light chain 3), which is the homolog of the yeast autophagy protein, Atg8. Acidified late endosomes and lysosomes fuse with these nascent vacuoles to form the autolysosome; inhibitors of the $V\text{-(H}^+)$ ATPase, such as bafilomycin, inhibit fusion with both components. Deficiency of the E1 ubiquitin-activating enzyme also impairs clearance of the late autophagic vacuoles – critically implicating protein ubiquitination in autophagy. Continued acidification, with activation of the complement of lysosomal hydrolases initiates digestion of the segregated contents; these disintegrate, with formation of a multi-vesicular body containing electron-dense debris which is ultimately consolidated to an auto-fluorescent core or residual body (Piper and Luzio, 2001). Lysosomal diseases associated with deficient hydrolase activity or defective cofactors, or treatment with lysosomal

enzyme inhibitors, lead to the accumulation of late autophagic vacuoles stuffed with incompletely processed cytoplasmic contents and membranous debris.

Autophagy and the Lysosome in Energy Economy and Nutrient-Sensing

Autophagy

Autophagy provides nutrient precursors retrieved from prior biosynthetic investment under conditions of sufficiency; organelles and other cellular constituents serve as source that can be readily recovered as a working currency under conditions of metabolic stress and particularly when the supply of nutrients is limited. Autophagy is thus characteristically stimulated by starvation and allows the cell to adopt a parsimonious attitude to energy potential and nutrient stores.

Disuse of muscles, inflammatory conditions associated with fever, glucagon or thyroid hormone action, as well as sympathomimetic stimulation, also enhance autophagy in different tissues. Hence, what was formerly considered a 'housekeeping' function of the lysosome proves to be a highly regulated and adaptive process (Ravikumar *et al.*, 2010).

Perceptions of the rôle of the lysosome in metabolic control are changing rapidly. Over the last decade, a body of research, including discoveries in the laboratories of David Sabatini on the protean functions of mechanistic target of rapamycin complex (mTORC) (Sengupta *et al.*, 2010), and of Andrea Ballabio, has shown that the lysosome itself serves as a coordinating center which controls the clearance of cellular components in response to the demands for energy generation and biosynthesis of essential intracellular constituents. Identification of the controlling transcription factor TFEB for lysosomal protein expression and biogenesis is of signal importance (Sardiello *et al.*, 2009).

The multi-subunit serine/threonine protein kinase, mechanistic target of rapamycin complex 1 (mTORC1), regulates homeostasis by coordinating metabolism in response to nutrient, energy, and oxygen availability, as well as signaling for growth and proliferation from growth factor–receptor interactions. Energy-sensing of mTORC1 is effected through the ATP/AMP energy charge which if below a threshold will engage the kinase, 5'AMP-activated protein kinase (AMPK), that is activated under conditions of reduced ATP and elevated AMP availability. Autophagy is also orchestrated by the reduced energy charge which favors inhibition of mTORC1 by phosphorylation and allows coordination of overall nutrient input with the demands for formation *de novo* of molecules critical for cell survival. AMPK in turn influences protein synthesis; specific phosphorylation of a target serine residue inactivates TSC2 and also the protein raptor which prevents recruitment of mTORC1, stimulates autophagy, and arrests initiation of protein synthesis at the level of eIF-2 α (Sengupta *et al.*, 2010; Sardiello *et al.*, 2009; Settembre *et al.*, 2013; Proud, 2006).

Autophagy linked to nutrient supply is regulated by a signaling network susceptible to stimulatory as well as inhibitory inputs. The TFEB is induced by starvation and mediates an adaptive homeostatic response (Settembre *et al.*, 2012). Apart from mTORC1, several kinases have been shown to phosphorylate TFEB, including extracellular signal-related kinase 2

(ERK2) and an isoform of protein kinase C (PKC β 95). Phosphorylation of serine at position 142 by ERK2 and of serine 142 and serine 211 by mTORC1 determines the subcellular localization of the nuclear transcriptional factor; it is cytosolic when phosphorylated and translocates to the nucleus when dephosphorylated at these residues. When the supply of nutrients is adequate, TFEB interacts with a group of cellular regulatory molecules newly termed the lysosome nutrient sensing (LYNUS) machinery. This detects nutrient signals via the v-(H⁺) ATPase complex, and is subject to phosphorylation control mediated by (mTORC1) on the cytosolic surface of lysosome. In the presence of nutrients and growth factors, mTORC1 is a strong inhibitor of autophagy. When the mTORC1 kinase function is activated, autophagy is inhibited: this activation requires the interaction of numerous proteins, including RAG GTPases and the Ragulator complex which are assembled at the lysosomal membrane (Sengupta *et al.*, 2010).

Cell growth is an anabolic process also coordinated by mTORC1; this involves enhanced translation of mRNA in response to the availability of signaling nutrients such as amino acids (Proud, 2006). Not only does mTOR-mediated phosphorylation of the binding factor 4E-BP1 render eIF4E available to bind eIF4G and promotes formation of functional initiation complexes, but phosphorylation activates elongation factors and ribosome biogenesis. However it is also clear that at the same time mTORC1 suppresses the breakdown of cellular components by autophagy, thus coordinating biosynthesis and degradation (Sengupta *et al.*, 2010; Settembre *et al.*, 2013). While it has long been understood that an essential pathway for sensing nutrient status is the master growth regulator mTORC1, the mode by which it is coupled to the nutrient signals and the lysosome has not until recently been recognized. Recent discoveries provide a logistical point of interaction between the requirements for cell proliferative responses through growth factors and release of amino acids and other intracellular building blocks during autophagy.

Growth factor signaling

Autophagy is regulated by a signaling network susceptible to input from discrete and distinct metabolic influences. Binding of insulin and related hormones to their cognate receptors activate the mitogen-activated protein kinase (MAPK) signaling mechanism through the Raf-1–MEK1/2–ERK1/2 pathway. Distinct from mTORC1 pathway, this mechanism ensures that the master regulator of lysosomal biogenesis TFEB can be preferentially phosphorylated by separate mechanisms so that lysosomal protein synthesis and autophagy are not initiated above constitutive rates (Proud, 2006; Settembre *et al.*, 2011).

Mechanistically mTORC1 controls protein synthesis, coordinating signals related to nutrients and energy status – as well as those received from insulin and other growth factor receptors – to regulate metabolic fluxes involving biosynthesis and catabolism (Laplanche and Sabatini, 2013). Ultimately, this system controls cell growth and proliferation. Insulin-like growth factors may also act through the receptor tyrosine kinase Akt/PKB signaling to activate mTORC1. Many signals received by mTORC1 are orchestrated by a heterodimeric tumor suppressor complex TSC1/TSC2 (tuberous sclerosis complexes 1 and 2) that inhibits the guanosine triphosphatase, Rheb; this in turn activates mTORC1 protein

kinase activity and hence protein synthesis. Mitogens such as insulin-like growth factor 1 activate the mitogen activated protein kinase/extracellular kinase (MAPK/ERK) pathway, which can inhibit the TSC1/TSC2 complex, thus stimulating mTORC1 and inhibiting autophagy. Energy-sensing of mTORC1 is effected through the ATP/AMP energy charge which if below a threshold will activate the kinase, AMPK, that in turn influences protein synthesis and by means of a specific phosphorylation of a target serine residue, inactivates TSC2 and also the protein raptor. This prevents recruitment of mTORC1, stimulates autophagy and arrests initiation of protein synthesis at the level of the initiation factor 2 subunit, eIF-2 α (Sengupta *et al.*, 2010; Sardiello *et al.*, 2009; Proud, 2006; Settembre *et al.*, 2011, 2012, 2013; Laplanche and Sabatini, 2013).

Amino acid signaling

Autophagy is regulated by a signaling network susceptible to stimulatory and inhibitory inputs. mTORC1 integrates signaling by means of phosphoinositol 3-kinase (PI3 kinase) and pathways sensitive to amino acids. Amino acids are assembled into proteins but also serve as metabolic intermediates in other biosynthetic reactions; amino acids strongly influence an over-arching control switch that regulates the cellular supply of energy and key nutrients (Bar-Peled and Sabatini, 2014). This pathway ultimately involves the lysosome to enact the molecular directives of the multicomponent protein kinase and master growth regulator, the mTORC1.

Binding of insulin and related hormones to their cognate receptors activates the mTORC1 pathway, leading to inhibition of autophagy. In contrast to growth factor signaling, amino acids may signal to mTORC1 by inhibiting Raf-1–MEK1/2–ERK1/2 and so also inhibit autophagy. A critical factor for understanding metabolic control through the mTORC1 pathway resides in the observation that growth factors do not effectively activate mTORC in the absence of amino acids.

Amino acids influence the interaction between mTORC1 and a distinct family of four small GTPases. These so-called Rag GTPases promote the intracellular localization of mTORC1 to the proximity of its activator, Rheb, on the cytoplasmic surface of the lysosome. It has been recently shown that the vacuolar H⁺-adenosine triphosphatase is required for amino acids to activate mTORC1. The v-ATPase interacts with the Ragulator, a complex that serves as a scaffold to bind the Rag GTPases to the lysosome (Zoncu *et al.*, 2011).

Signaling via free amino acids, especially leucine and lysine (and possibly glutamine) occurs within the lysosomal lumen – a process dependent on the putative amino acid carrier, human member 9 of the solute carrier family 38 (SLC38A9) present in the lysosomal membrane and of which a unique cytoplasmic segment forms part of the conformation-specific Ragulator-Rag GTPases scaffold. Experimental mutagenesis and cellular expression of a defective amino acid carrier shown that SLC38A9 is an essential component of the nutrient-sensing machinery by which leucine and other intralysosomal amino acids released by proteolysis are able to permit activation of the mTORC1 kinase control pathway. Allosteric control exerted by the carrier protein on mTORC activity transduces signals indicating the abundance of key nutrients

released in the intralysosomal compartment – the system thus ensures permissive regulation of autophagy and organelle biogenesis as well as overall metabolic control by sensing at the core of the cell (Rebsamen *et al.*, 2015).

Lysosomal Diseases

Studies in several populations show that a range of 1 per 2315 – 7700 living infants are born with an inherited lysosomal disease (depending on the method of ascertainment (Mechtler *et al.*, 2012; Poupetová *et al.*, 2010)), representing a large burden to the individual, their carers, and society. Although the defect is present at birth, the diseases typically appear later. Clinically diverse, the rate of progression and effects on the individual vary greatly. While the manifestations of lysosomal diseases often include enlargement of the visceral organs, disturbed function and infiltration of the lungs and kidneys for example, often accompanied by skeletal effects. In about two-thirds of the lysosomal diseases, neurological deficits occur.

Clinical Conspectus

Arguably, the first disease in humans now known to be a lysosomal disorder was reported in four siblings from an isolated community in Norway by Otto Stengel, in 1826. Stengel gave a convincing description of impaired vision leading to blindness, cognitive decline, and early death. His description indicates a classical and most frequent form of juvenile neuronal ceroid lipofuscinosis (CLN3) – now seen as one of 14 genetically distinct disorders with common clinicopathological features including neurodegeneration with seizures, in the family of neuronal ceroid lipofuscinoses (Haltia *et al.*, 2011). Mutations in a protein, CLN3, particularly expressed on endosomal–lysosomal membranes, but with as yet unknown function, are responsible for this disease.

Pompe disease

Pompe disease in infants with massive cardiac hypertrophy and hypertonia due to profound skeletal muscle weakness was first described by Joannes Cassianus Pompe in CE 1932. The disease had a rapidly fatal outcome. Pompe disease (known also as glycogenosis II) has iconic significance since it was the first inborn error of the lysosome to be so identified. Large quantities of glycogen are deposited in muscle, including the tongue. Hepatic enlargement also occurs in affected infants. Acid maltase is profoundly deficient in affected infants with Pompe disease; patients with the disease beyond infancy usually have residual acid maltase activity and attenuated clinical variants characterized by a proximal skeletal myopathy and sparing of the heart but with weakness of the diaphragm leading to respiratory failure.

When manifest in children and adults, poor athletic performance and occasionally delayed achievement of developmental milestones are observed: the spine is hypermobile due to weakness of proximal muscles with inability to rise from the squatting position or maintain the upper limbs in an extended position; while the onset of symptoms varies

between childhood and up to the age of 60 years, few patients give a lifelong history. Ultimately, respiratory muscle weakness ensues with retention of carbon dioxide as a result of ventilatory failure. Inability to swallow solids is the result of impaired function of the voluntary pharyngeal muscles (van den Hout *et al.*, 2003).

Specific treatment has been introduced for Pompe disease in the form of recombinant acid maltase administered by infusion. In infants where acid maltase is absent, immune reactions to the infusions of the wild-type acid maltase occur and this may lead to treatment failure (Kishnani and Beckenmeyer, 2014). Otherwise survival is prolonged beyond infancy and the child may have normal growth, although non-muscle manifestations in heart, viscera, and kidney with prominent endothelial disease and late complications in the nervous system may ultimately prove fatal.

Tay-Sachs disease

Tay-Sachs disease was originally described as a rapidly fatal neurodegenerative condition that is also known as GM2 gangliosidosis, in a young child almost certainly of Ashkenazi origin from Whitechapel, East London, in CE 1881 (Tay, 1881). The disease remains a paradigmatic example of severity and also heterogeneity at many levels: Waren Tay noted progressive loss of sight, reduced muscle tone, poor movement, and loss of cognitive ability; he later reported on the familial nature of the condition. Owing to the near-specific retinal findings in the index patient with the ‘cherry red spot’ (representing pale retinal ganglion cells near the macula), Tay’s identification is unambiguous. Bernard Sachs, a neurologist in New York, reported the strong predilection for Ashkenazi Jews. An early indication of the lysosomal nature of Tay-Sachs disease was revealed by Sachs’s subsequent neuropathological studies of children with ‘amaurotic family idiocy,’ showing involvement of nearly all neurones by a process that distorts dendrites with cytopathic changes in neurones characterized by prominent intracytoplasmic bodies in the perinuclear region – electron microscopy of which, years later, revealed abnormal lysosomes (Terry and Korey, 1960). Tay-Sachs disease is a classical example of an extremely severe neurodegenerative lysosomal disease in infancy marked by strong ethnic associations (several in non-Jewish communities) and with effective prenatal screening programs established globally for at-risk individuals (Kaback and Desnick, 2011).

Gaucher disease

Gaucher disease, also over-represented in the Ashkenazim, is a sphingolipid disorder biochemically related but clinically distinct from Tay-Sachs disease. First reported in a doctoral thesis in the University of Paris (1882) by P.C. Ernest Gaucher in a 34-year-old woman who died in Paris in CE 1881, it causes massive enlargement of the liver and spleen with anemia and bleeding. These characteristic features are now readily ameliorated by functional complementation using the purified lysosomal glycoprotein (acid β -glucosylceramidase encoded by the GBA1 gene) that is deficient in the condition; the therapeutic enzyme is remodeled to display terminal mannose residues which mediate protein uptake by specific surface receptors on the pathological macrophages – a principal focus of the disease in viscera (Deegan and Cox, 2012).

Gaucher disease provides a spectacular example of the successful application of rational molecular understanding to therapeutic research with beneficial outcomes in an otherwise life-shortening and ultra-rare (orphan) disease: large biotechnology revenues have been generated – realizing the aims of the 1983 US Orphan Drug Act. However, after introduction of salutary targeted enzyme augmentation, the panethnic and protean nature of Gaucher disease has been revealed. Now viewed as a classical example of a multisystem lysosomal disease principally due to unitary genetic determinants, Gaucher disease presents challenging comorbidities. These include several unusual cancers (especially myeloma and B-cell lymphoma) (Weinreb and Lee, 2013) and complex and poorly understood neurological phenomena, including Parkinson disease and Lewy body dementia – late-onset neurological complications occurring in otherwise apparently healthy heterozygous carriers not only in pedigrees affected but in the general population, including those with Ashkenazi Jews but also in other ethnic groups, suggesting the influence of dominant-negative mutant GBA1 alleles (Shapira, 2015). With commercial introduction of effective treatments for this ultra-rare disorder, accretion of clinical experience based on cohorts of patients who attend expert clinical centers has, in an era of biopharmaceutical success, led in the treatment era to several unexpected mechanistic discoveries – beyond this, lies the expectation of advanced therapies based on fundamental understanding of the pathogenesis of lysosomal disorders.

Nomenclature

Classification of Inborn Errors of the Lysosome

At least 70 inborn errors of lysosomal biogenesis and function (including lysosome-related organelles) are reported. As powerful methods for ultra-rapid DNA sequencing are introduced for precise diagnosis of rare diseases and with intensive study of lysosomal membrane proteins (Saftig and Klumperman, 2009), this list is growing. Lysosomal diseases may be classified according to the nature of the biochemical consequences of the defect (usually pathological storage of a given macromolecular substrate and its precursors) or according to the defective molecular function induced by the given genetic defect; while this provides a better interpretation as to basic causation, for optimal practical understanding, a reconciliation of the two systems is desirable.

Inborn errors of lysosomal metabolism may be classified biochemically. While useful, this classification includes diverse conditions attributed to mutations at single loci but with multifarious clinico-pathological effects. The incomplete taxonomy of lysosomal diseases in part reflects the history of their individual discovery: it includes identification of the principal storage molecules and their relationship to the disrupted cellular biology. Each disorder reveals aspects of the many-faceted rôle of lysosomes in the remodeling of intracellular components through autophagy, recycling of exogenous materials as well as nutrient- and energy-sensing – functions linked to biological economy. While a more impartial genetic classification might appear attractive, defects in many non-lysosomal proteins that interact dynamically to sustain and

control the lysosomal network will be needed before a comprehensive taxonomy can be agreed.

- Major classes related to biochemical abnormalities include:
 - Mucopolysaccharidoses
 - Sphingolipidoses
 - Glycoproteinoses
 - Glycogenosis with or without autophagic debris
 - Conditions with multiple classes of storage material.
- Functional defects include:
 - Deficiency of a given acid hydrolase
 - Abnormal posttranslational modification of lysosomal proteins
 - Deficiency of an activator or protein cofactor
 - Defective lysosomal membrane or transporter protein
 - Disturbed biogenesis of lysosomes or lysosome-related organelles.

Identification of the First Inborn Disease of the Lysosome

Although the lysosome was a chance discovery by Christian de Duve, it was his former colleague, Henri-Géry Hers (also a Belgian physician-investigator) who identified the first inherited disease of the lysosome (Hers, 1963). Pompe disease is a fatal condition in which cardiomyopathy and skeletal myopathy are accompanied by excess glycogen deposition in the affected tissues. Notably, the histochemical properties of the excess glycogen appeared normal, including its chromogenic reaction with iodine/potassium iodide. Hers investigated the enzymatic activities related to the metabolism of glycogen that had been explored by Gerty and Carl Cori at Washington University School of Medicine. These investigators shared the 1947 Nobel prize for Medicine or Physiology. Of note, Carl Cori was a scientific mentor of de Duve; Gerty Cori, née Radnitz, was a former pediatrician and had encountered glycogen storage disorders – much later in the US identifying or correctly postulating the enzyme defects in four distinct types. This body of work provided the methodological platform for Hers's studies in tissue biopsy specimens obtained from patients with generalized glycogenosis, Pompe disease – previously classified by Gerty Cori as glycogen storage disease type II (notably without a biochemical explanation) (Cori, 1952).

Hers found that activities of branching enzyme, debranching enzyme, glucose 6-phosphatase, and glycogen phosphorylase were within the healthy reference range; however, in a series of experiments, in part to investigate glucosyltransferase activities related to the possible debranching enzyme postulated by W.H. Whelan, the activity of a previously unknown glycosidase in liver tissue was found to be deficient in patients with Pompe disease. This 'maltase' had a pH optimum of 4 and when control tissues obtained from patients with other glycogen storage diseases were examined, acid maltase activity was found to be selectively deficient in Pompe disease (Hers, 1983). Hers and colleagues subsequently showed that acid maltase present in rat liver had properties typical of a lysosomal hydrolase: activity in fresh tissue homogenates co-sedimented with the classical lysosomal marker enzyme, acid phosphatase; it was moreover found that after freeze-thawing or addition of mild non-ionic detergent (digitonin), the complement of lysosomal

acid maltase activity was liberated into 'soluble' supernatant fractions (Lejeune *et al.*, 1963). Pierre Baudhuin, an electron microscopist, reported the presence of intralysosomal and extralysosomal glycogen deposits in a biopsy sample obtained from the liver of a patient with Pompe disease (Baudhuin *et al.*, 1964).

Correlation of biochemical and structural abnormalities – organelle pathology

Prompted by the early introduction of fibroblast cultures obtained from skin biopsies as a technique for refined study of heritable disorders of connective tissue, Danes and Bearn showed that fibroblasts cultured from patients with Hurler syndrome (MPS I) showed cellular metachromasia on staining with various organic dyes (Danes and Bearn, 1965), with expression of the cellular defect in a manner compatible with the Lyon hypothesis of X-inactivation in fibroblasts from patients with X-linked disease (Hunter syndrome, MPS II). It is now known that these inherited metabolic diseases are associated with the lysosomal accumulation ('storage') of glycosaminoglycans. Hers later collaborated with François van Hoof, who had studied tissues obtained from patients with mucopolysaccharidosis (MPS) by electron microscopy. Having observed abnormal ultrastructure in the liver of patients with MPS I (Hurler disease), Hers and van Hoof determined the activities of lysosomal enzymes in mucopolysaccharidoses and later, the glycoprotein disorder, fucosidosis. At this time, the excess glycosaminoglycans were postulated to be the consequence of overactive biosynthesis. The biochemical findings were compatible with studies of ultrastructure by electron microscopy, which revealed prominent intracellular membrane-bound inclusion bodies representing the effects of the disease in the lysosomal compartment (Baudhuin *et al.*, 1964; Van Hoof and Hers, 1968).

Inborn errors of the lysosome

The concept of inborn errors of lysosomal function was formally enunciated by Henri-Géry Hers in CE 1965 (Hers, 1965). Thus numerous defects in the recycling of cellular macromolecules were classified as 'lysosomal storage diseases.' While the general potential for access of proteins to the lysosomal compartment had been realized earlier by de Duve, the enzyme defects soon to be found responsible for several lysosomal diseases have important consequences for diagnosis and understanding but also in the context of later discoveries by E.F. Neufeld, W.S. Sly, P.D. Stahl, R.O. Brady, and others that provide the experimental basis for specific therapy directed to the lysosome. De Duve later noted that the research by H.-G. Hers: "... elucidated, with important consequences for diagnosis, prevention and therapy, a vast chapter of pathology that had remained totally mysterious ..."

Pathogenesis of Lysosomal Diseases

Understanding of the molecular pathogenesis of lysosomal diseases is generally rudimentary, and despite increasing knowledge about the primary genetic defect, it is now clear that most lysosomal defects represent individual pathological domains with a few shared but many unique determinants

that defy general description. Here below, some basic aspects of pathogenesis and storage are set out but space does not permit comprehensive discussion; for more in-depth information please refer to recent reviews and references therein (Lieberman *et al.*, 2012; Klein and Futerman, 2013; Cox and Cachón-González, 2012; Platt *et al.*, 2012; Morgan *et al.*, 2011).

Lysosomal storage

A noteworthy feature of the lysosomal breakdown of cellular macromolecules is that the process usually occurs in a stepwise fashion and is initiated at terminal units, for example, glucose units in glycogen or nonreducing terminal sugars in the glycosaminoglycans and glycosphingolipids. Should the lysosome fail completely to digest the terminal unit, then subsequent sequential breakdown of serial units in the macromolecular substrate is arrested. However, at the same time, cellular biosynthesis of the macromolecule and its presentation to the lysosomal compartment via autophagy and endocytosis continues – thus inducing a buildup of the undegraded material as well as precursor molecules that have been generated in preceding enzymatic steps. Generally, the immediate consequence of the deficiency of any given acid hydrolase is the accumulation of material into an expanded lysosomal space which, as a result of unusual staining properties (e.g., metachromasia in the fibroblasts cultured from patients with MPS (Danes and Bearn, 1965)), ultimately alerts the microscopist. Electron microscopy reveals a distorted membranous compartment representing a greatly expanded lysosomal network within the ultrastructure of the cell (Baudhuin *et al.*, 1964).

Effects of Lysosomal Storage

Lysosomal storage may arise for reasons other than the direct or indirect impairment of digestive function: defective transport of the products of lysosomal digestion due to mutations in carrier proteins may be responsible. A classical example is cystinosis, where mutations in the transmembrane protein, cystinosin, lead to retention of cysteine – a product of intralysosomal proteolysis and which dimerizes to form crystalline oxidized cystine aggregates within the lysosomal compartment (Nesterova and Gahl, 2013). For reasons not completely understood, the condition usually first induces disease of the proximal renal tubule of the kidney but if untreated, proceeds rapidly to induce a multisystem disorder and renal failure; intracellular deposits of cystine are readily seen by light microscopy in many tissues including the thyroid gland, skeletal muscle, and heart – early on in the illness, crystalline deposits are readily visible in the cornea which, if untreated, cause ocular irritation and impaired vision.

Ultimately, once the capacity for retaining the array of cellular macromolecules is exceeded, many lysosomal functions become compromised. While simple observation of the diseased tissue may show distorted and hypertrophic cells with an expanded lysosomal space, often in a perinuclear distribution, vary rarely does storage material account directly for the effects on the manifestly diseased organ. For example, in Gaucher disease, where the spleen at 6 l may be enlarged more

than 40-fold above the normal adult volume of less than 150 mL, the additional tissue cannot be accounted for by the excess storage material – in this case principally β -glucosylceramides (which account generally for only a few tens of grams of the several kilograms of excess tissue mass). While this quantitative disparity has long been known, in the context of widespread inflammatory conditions with hyperplasia and multiple tissue adaptations related to an inflammatory response in the face of biochemical storage, it remains true that in most instances the consequential effects of the storage are poorly understood in biochemical or molecular terms; they are reported principally as part of the descriptive vocabulary of inflammatory and other histopathological changes, due to the release of cytokines, macrophage activation, edema, cell loss, fibrosis, and altered vascularity.

Lysosomal Diseases and Disturbances of Autophagy

Pompe disease demonstrates the rôle of autophagy in glycogen remodeling

Pompe disease, the first lysosomal disease to be biochemically characterized – known alternatively as glycogen storage disease Type II – affects a key cellular energy store in muscle, liver, brain, and endothelial cells. Glycogen is an intracellular metabolite and important repository of energy central to cellular anabolism and storage on the one hand, and energy-yielding catabolic pathways activated by nutrient crises on the other. Given the rôle of the lysosome in the continual remodeling of glycogen, as well as the recycling of protein and complex lipid components in the cell, accompanied by liberation of internal resources through autophagy, it is clear that the organelle plays a critical part in cellular homeostasis.

Glycogen is a highly arborized polymeric structure or dendrimer originating from a single tyrosine-linked protein core of glycogenin. Each linear stretch contains about 13 glucose residues and, except for the outermost layer, carries two branches of the same length that are attached 3–4 glucose units apart. The high density of the branches in each glycogen molecule favors ready access of the enzymes and regulatory proteins involved in fine metabolic control of energy and glucose supply at the termini. Crowding in the outer branches of the glycogen polymer ultimately leads to steric hindrance of branching enzyme, so that the molecule is limited to about 55 000 glucose units with a calculated MW $\approx 10^7$ Da (Cori, 1952).

Metabolic studies show that glycogen is degraded within a few hours of synthesis, but slight abnormalities in the molecular nanostructure due to faulty formation of its α -1,6 branches lead to condensed particles with over-packed polyglucose chains in the outer reaches which impede glycogenolysis – which is dependent on a coordinated multi-enzyme process. Thus, constitutive and random remodeling of glycogen by lysosomal acid maltase (Devos and Hers, 1980), with α -1,4 glucosidase, α -1,6 glucosidase as well as glucoamylase activities, removes nonfunctioning structural domains and maintains the integrity of cellular glycogen, thus preserving an accessible source of energy with a low osmotic burden in metabolically intense cells. When autophagic function is impaired in Pompe disease, the undegraded residues assume a characteristic pathological appearance: there are prominent

vacuolar spaces engorged with glycogen and other debris, including remnants of cellular organelles and membranes (Lieberman *et al.*, 2012) – features observed in Pompe and Danon disease but increasingly recognized as pathological consequences of many lysosomal diseases.

Detailed studies in Pompe disease immediately revealed the dynamic rôle of the lysosome in cellular biology and added further understanding of autophagy – itself an activity designated from the outset by de Duve. In Pompe disease, glycogen of a near-normal structure accumulates principally in a pathological intracellular network corresponding to the lysosomal compartment deficient in acid α -glucosidase (acid maltase) activity. Thus, not only does the lysosome serve as a recycling center for other effete organelles and membrane fragments, but under resting metabolic conditions, continually remodels cytosolic macromolecules with an apparently normal composition. In the case of glycogen, its physiological rôle is dependent on constitutive remodeling by acid maltase – without which its key function as a dynamic and accessible energy source is lost.

Coordination of Lysosomal Biogenesis and Autophagy – Revelations from Human Pathology

The existence of a process for coordinating transcriptional expression of lysosomal proteins had long been suspected, but identification of the responsible mechanism depended on a series of studies prompted by a clinico-pathological observation in human lysosomal diseases. For many years, those lysosomal diseases associated with extensive storage of partially or completely undegraded parent macromolecules have been known to have an increased tissue activities of lysosomal hydrolases and other proteins associated with pathological expansion or hypertrophy of the lysosomal compartment. The enhancement of acid hydrolase activity (as well as protein abundance) of lysosomal proteins is typically found to be two- to threefold in plasma and often much greater in diseased tissues.

The explanation for increased lysosomal protein expression had long been puzzling until a gene network regulating lysosomal biogenesis and function was identified by Sardiello and colleagues in the Ballabio laboratory. These investigators explored the possibility of a coordinated control system leading to enhanced transcriptional activity common to lysosomal proteins. Using pattern discovery analysis of the promoter region of genes encoding 96 lysosomal proteins, a palindromic decanucleotide motif (termed the coordinated lysosomal expression and regulation element, CLEAR) was identified. The CLEAR element is able to bind to a nuclear transcription factor, TFEB, which is a member of the basic helix-loop-helix leucine-zipper family, sub-family (MiT/TFE), and also a target for silencing by a micro RNA, miR-128 (Sardiello *et al.*, 2009).

Subsequent searches for genome-wide TFEB *cis*-acting motifs indicated that TFEB activates transcription of many target lysosomal genes. Cellular overexpression of TFEB induced biogenesis of lysosomes with expansion of the compartmental network. Enhanced expression of TFEB stimulates lysosomal degradation of glycosaminoglycans and other macromolecular substrates (Palmieri *et al.*, 2011). The transcription factor induced expansion of the pool of lysosomes in

the proximity of the plasma membrane and promoted their fusion at the membrane by raising intracellular Ca^{2+} concentrations with activation of the lysosomal Ca^{2+} channel, mucolipin 1, MCOLN1 which is mutated in mucopolipidosis type IV (Medina *et al.*, 2011).

Reciprocal Signaling between mTORC1 and TFEB on the Lysosome

Autophagy is stimulated by starvation or the withdrawal of growth factors; it is also stimulated by oxidative stress and protein aggregation. While inhibition of mTORC1 stimulates autophagy, the ensuing proteolysis with release of amino acids after autophagy will reactivate mTORC1, and lysosome numbers and compartmental volume will be restored (Yu *et al.*, 2010). As shown, many proteins downstream of mTORC1 contribute to the regulatory control program of autophagy. In the default state of nutrient starvation, the (mTORC1) is localized in the cytoplasm and is dispersed when amino acids are experimentally depleted. In the presence of supplemental amino acids, cellular mTORC1 has a punctate lysosomal localization and autophagy is inhibited (Settembre *et al.*, 2011). In the presence of nutrients, when mTORC1 is translocated to the lysosomal surface, it is able to phosphorylate critical serine residues (including ser 142) on TFEB which impede nuclear entry of the transcription factor. In this way co-localization of the transcription factor permits co-regulation with the master regulator of growth control (mTORC1) – thus simultaneously regulating lysosomal biogenesis and autophagy. In a reciprocal manner, when mTORC1 is inhibited by rapamycin (sirolimus) and everolimus, or by starvation, dephosphorylated TFEB is able to translocate to the nucleus – thereby increasing co-ordinate transcription of genes which encode key proteins involved in autophagy and lysosomal biogenesis. When after starvation, cultures are supplemented with serum, amino acids, insulin, or epidermal growth factor, TFEB nuclear translocation is inhibited compared with the location in cells maintained in starvation medium alone. This suggests that TFEB activation is controlled by a signaling mechanism which is sensitive to nutrient as well as growth factors.

Since starvation induces the transcription of several autophagy genes whereas inhibition of mTORC1 does not, Settembre and colleagues investigated TFEB as a mechanism for activation of autophagy during starvation (Settembre *et al.*, 2011). As explained, without nutrient deprivation, TFEB has a cytoplasmic location, but under conditions of starvation the factor is rapidly translocated to the nucleus; cytosolic TFEB from starved cells had a lower molecular size – a shift occurring transiently and reversibly after relief of starvation with relocation of TFEB from the nucleus and suggesting phosphorylation control. Nuclear localization and activity of TFEB is regulated by serine phosphorylation mediated by the extracellular signal-regulated kinase 2, ERK2, which in turn receives signaling influences from the mitogen-activated protein kinase (MAPK1) whose activity is determined by hormones and extracellular growth factors via the Raf-1–MEK1/2–ERK1/2 pathway. Overexpression of TFEB in HeLa cells and other mammalian cells increases autophagosome abundance and expression of the LC3-II protein, which forms part of the autophagosome membrane. Excess autophagosomes persist after treatment with the vacuolar $\text{v}-(\text{H}^+)$

ATPase inhibitor, bafilomycin, which inhibits autophagosome and LC3-II degradation – indicating that formation of autophagosomes was stimulated *de novo*.

When starved cells growing in normal medium were supplemented with agents, including rapamycin that inhibit either the mTORC, phosphatidylinositol 3-kinase–AKT, or MAPKs, only inhibition of MAPKs was found to induce translocation of the TFEB protein to the nucleus; inhibitors of AKT and mTOR had no effect. Latterly there is evidence that the fundamental mediator implicated in this process is the steady state concentration of Ca^{2+} ions (Medina *et al.*, 2015). Ca^{2+} release from the lysosomal compartment is induced by interactions of TFEB with the phosphatase, calcineurin; thus clinical inhibitors of calcineurin such as ciclosporin, may allow interdiction of these basic cell processes with possible benefit on lysosomal pathology. The master regulatory protein for lysosomal biogenesis, TFEB, also stimulates exocytosis of lysosomal contents by transcriptional effects. This process, which discharges lysosomal contents through docking and fusion of the organelle with the plasmalemma, is associated with dynamic enhancement of lysosomal trafficking and elevation of intracellular Ca^{2+} ions (Settembre *et al.*, 2013).

These recent studies, realized in mammalian cells, provide a convincing mechanistic link between nutrient supply, lysosomal expansion, and the initiation of autophagy under conditions of cellular stress or growth factor signaling. However, while many interacting components have been discovered, the regulatory hierarchies within the interrelated components assembled on large scaffolds in the cell present a puzzling intricacy; furthermore, the contribution of disturbed autophagy and nutrient-sensing to the energetics of the whole individual organism suffering from a particular lysosomal disease is incompletely understood (see Section ‘Gaucher disease’).

Danon disease – an intrinsic disturbance of macroautophagy

Danon disease was identified in CE 1981 in patients with abnormalities of glycogen storage in the heart and skeletal muscle previously thought to have Pompe disease; the patients were found to have normal acid maltase activity. Inherited as an X-linked disorder, heterozygous females die prematurely of progressive cardiomyopathy; in hemizygous males, cognitive impairment, skeletal- and cardio-myopathy is severe and death occurs usually by the age of 25 years. Danon disease is due to mutations in the lysosomal membrane protein LAMP-2 (Malicdan and Nishino, 2012), one splice variant of which (LAMP-2A) is a receptor implicated in chaperone-mediated autophagy. Histopathological examination shows vacuolar myopathy with large intracellular spaces filled with glycogen and other cellular debris, including mitochondria, peroxisomes, ribosomes, and membrane fragments in association with a normal or high acid maltase activity. The pathological features include expanded autophagic vacuoles with characteristic double-unit membranes. In LAMP-2A deficiency, the uptake and degradation of proteins in neurons via chaperone-mediated autophagy is defective: this leads to the accumulation of aggregated complexes of protein such as α -synuclein and huntingtin in the expanded autophagic vacuoles. Danon disease reveals the critical rôle of LAMP-2

protein within the nervous system, as well as skeletal and cardiac muscle.

Other Lysosomal Diseases

Functional Classification defines five groups of lysosomal diseases, paradigmatic examples of each category of which are given below:

Deficiency of a Specific Acid Hydrolase

Gaucher disease

Occurring at any age, this is one of the more frequent lysosomal diseases, usually due to a catalytic deficiency of an acid β -glucosidase, β -glucocerebrosidase (D-glucosyl-N-acyl-sphingosine glucosylhydrolase, EC 3.2.1.45), encoded by the human GBA1 gene (Cox and Schofield, 1997; Grabowski, 2008). The enzyme, a lysosomal glycoprotein with a range of natural substrates that are mixtures of N-acyl-sphingosyl-1-O- β -D glucosides with varying acyl and sphingosine moieties, including those like β -glucosylsphingosine devoid of fatty acids; the enzyme cleaves glucosylceramide into glucose and ceramide. A very few patients with deficiency of the cognate sphingolipid activator protein (SAP-C) required for activity of the enzyme toward its natural sphingolipid substrates have been described. The enzyme, a lysosomal glycoprotein, is an acid β -glucosidase. SAP-C deficiency usually causes a severe disorder intermediate between Gaucher disease and metachromatic leukodystrophy but exceptional patients with disease restricted to the non-neuronopathic manifestations of Gaucher disease are reported.

Numerous mutations responsible for the enzymatic deficiency have been identified in the human GBA1 gene that encodes the β -glucosidase. Very rarely, infants are born with an almost complete lack of β -glucocerebrosidase activity and die within a few days of birth, or are stillborn due to skeletal deformities and loss of skin integrity, with sloughing of layers of scaly skin to cause a collodion-like appearance 'icthyosis lamellaris' – the explanation for this lies in the requirement of the aqueous barrier function of epidermal keratinocytes for very long-chain (C26–C36) acyl ω -hydroxylated ceramides of unusual structure whose biosynthesis is dependent on lysosomal GBA1 activity.

Infantile Gaucher disease (acute neuronopathic) is a very rare condition associated with death in the first year of life; neuronopathic disease is characterized by bulbar palsy due to neuronal cell death in essential mid-brain and pontine nuclei, a decerebrate posture (opisthotonus), and visceral enlargement. The neuronal pathology is associated with loss of eye movement control, respiration, and other visceral functions; it does not respond to any existing therapy.

Chronic neuronopathic Gaucher disease describes less severe forms of the condition occurring in children, adolescents, and young adults, such as supranuclear gaze palsies, incoordinate movement, nerve deafness, and a form of epilepsy known as myoclonic epilepsy with spasmodic involuntary jerking movements of the limbs leading to generalized seizures. This form of Gaucher disease is often stable for many

years but may deteriorate slowly, particularly if the spleen is removed in attempts to ameliorate the accompanying visceral manifestations. This form occurs sporadically in all populations, but particularly in non-European populations where it is the most common form of Gaucher disease, for example, in Arab populations, China, and Southeast Asia. A particular variant of chronic neuronopathic disease has been reported from a province of Northern Sweden, where all individuals are homozygous for a single point transition, at position c. 1448 T->C in exon 10 of the GBA1 gene leading to the missense mutation L444P [p.L483P]; this appears to have arisen by descent from a common Swedish ancestor in the CE sixteenth century and is the most frequent mutant GBA1 allele in most populations.

The most reported but not necessarily most frequent adult form of Gaucher disease as first described by Ernest Gaucher occurs in all populations but is over-represented in Jews of Ashkenazi origin, where a single transition c.1226 A->G, leading to the missense mutation, N370S [p.409S], in the GBA1 gene is most prevalent. The condition does not typically affect the nervous system initially, but the visceral and skeletal manifestations are prominent due to infiltration of the bone marrow, spleen, liver, and occasionally other organs such as the lung, with pathological macrophages ('Gaucher cells') with an alternative form of macrophage activation ('M2'). Characteristically, the condition presents with the consequences of reduced platelet and leukocyte cell concentrations, as well as anemia, with bleeding and splenic enlargement due to pooling and increased destruction of the formed elements of the blood in this macrophage-rich organ. Episodes of acute pain occur in the bones, particularly during growth, followed by necrosis of the bone with later effects on the alignment and integrity of large joints including cartilage. The disease causes stunting of growth in children and delayed puberty with infantilism and lack of matrix and reduced bone mineral content – 'osteoporosis.' While the reduced abundance of circulating blood cells can be temporarily overcome by removing the spleen, this not only induces susceptibility to bacterial infections, but is associated with disabling and more frequent attacks of osteonecrosis.

Comorbid associations of Gaucher disease – the link to common disorders

Energy metabolism in lysosomal diseases

The extent to which the disruption of metabolic homeostasis accounts for cell death and tissue injury in the lysosomal storage diseases is unclear; however disturbed autophagy is likely to affect the metabolic economy of tissues as well as remodeling of glycogen.

An example of disturbed energy metabolism in a lysosomal disease has been well documented in one of the most common diseases, Gaucher disease – of note also, in milder variants that are not associated with neurological manifestations. Indirect calorimetry studies show greatly increased resting energy expenditure in these patients (increased up to 50% compared with that predicted for age, sex, and height and weight). Muscle mass is reduced. In one study, the abnormality was correlated with visceral enlargement, suggesting a relationship to disease bulk due to inflammatory changes and infiltration with pathological macrophages (Barton *et al.*,

1989). These metabolic changes may in part explain the prominent growth retardation observed in children with Gaucher disease; the relationship to the disease is demonstrated by salutary growth responses to introduction of enzyme augmentation therapy – and durable increases in body mass (often >10%) in similarly treated adults.

Disturbed immunity (B-cell lymphoma and myelomatosis)

Gaucher disease is a multisystem disorder, accompanied by numerous plasma and metabolic abnormalities. In the untreated state, the disease shortens life, even when splenectomy has not been done. Co-morbidities include increased frequency of autoimmune conditions; a polyclonal immunoglobulin proliferative response associated with monoclonal immunoglobulin paraproteins – and ultimately increased frequency of B-cell lymphoproliferative disorders leading to B-cell lymphoma and multiple myeloma, the cause of which is not fully understood (Mistry *et al.*, 2013). This may reflect the release of cytokines from the pathological macrophages, or the presentation of the pathological sphingolipids in B-cells via the CD1d surface receptor by Type II natural killer T-lymphocytes (NKT) follicular lymphocytes that secrete cytokines responsible for the alternative activation of macrophages (IL-4,6,10, and 13).

Parkinsonism

Other noteworthy comorbidities of Gaucher disease in affected homozygotes or compound heterozygotes for mutations in the GBA1 gene include Parkinsonian manifestations associated with cognitive impairment and Lewy body dementia (Sardi *et al.*, 2015; Beavan and Schapira, 2013). A striking further observation is that a high frequency of Parkinsonian manifestations occur in parents of patients with Gaucher disease and other heterozygous first-degree relatives (Goker-Alpan *et al.*, 2004); no overt gene-dosage effect of the GBA1 mutations has been established. A further striking consequence is the recent discovery that Gaucher-associated mutations at the GBA1 locus are strongly associated with Parkinsonism in all populations – indeed, these GBA1 mutations have proved to be the strongest genetic determinants of Parkinson's disease (Sardi *et al.*, 2015). Examination of tissues from patients with Gaucher disease and Parkinson disease, as well as those with Lewy body dementia, with or without Parkinson's disease in whom GBA1 mutations have been inherited in heterozygous form, show co-localization of ubiquitin and α -synuclein, together with a core of immuno-reactive glucocerebrosidase in the Lewy body (Goker-Alpan *et al.*, 2010). Protein aggregation of the mutant glucocerebrosidase, together with abnormalities of glycolipid metabolism in association with the primary germline defect, appear to interact unfavorably in nigro-striatal neurones that are the pathological focus of extrapyramidal disease.

These findings were initiated by careful study of the clinical narrative of Gaucher patients with Parkinson's disease: now applied to Parkinson's disease and Lewy body dementia generally, they offer remarkable insight into the neurobiological importance of the lysosome. Evidence that individuals heterozygous for other mutations in other lysosomal proteins, which when mutated are responsible for less frequent lysosomal diseases (e.g., neuronal ceroid lipofuscinosis and Niemann–Pick disease Type C) are pre-disposed to Parkinsonism,

offer potential insights for better understanding of common neurodegenerative diseases with large societal burdens. As a corollary, scientific investigators would wish also that other glycosphingolipid disorders which are very rare but disabling, such as neuronopathic Gaucher disease and GM2 gangliosidosis, will not be excluded from the excitement to develop innovative medicines which may have applications far beyond the narrow perspective of the lysosome (Gahl, 2012).

Defects of Posttranslational Processing and Organelle Targeting

I-cell disease (mucopolipidosis types II and III)

This disease resembles severe Hurler syndrome (MPS type 1), but excess glycosaminoglycans are not present in the urine and cultured fibroblasts from the patients show unusually large, phase-dense inclusion bodies – inclusion cells (I-cells). Almost identical inclusions occur in a milder clinical variant, formerly known as pseudo-Hurler polydystrophy. Multiple deficiencies of acid hydrolases are found in the tissues, but are combined with elevated activities of the cognate enzymes in plasma and other body fluids. The terms mucopolipidosis II and III were later used to reflect the hybrid biochemical features of mucopolysaccharidoses and the sphingolipidoses. In this classification, I-cell disease was called mucopolipidosis II (MLII) and pseudo-Hurler polydystrophy was assigned the term mucopolipidosis III (MLIII). Inherited as autosomal recessive traits, genetic studies in MLII and MLIII revealed interrelated complementation groups that are distinct from other known lysosomal disorders (Leroy *et al.*, 2012).

Although these are very rare inherited disorders (<1 in 200 000 live births), their scientific study lies at the crux of understanding the molecular basis for lysosomal targeting of acid hydrolases based on receptor-mediated uptake of glycoproteins harboring a specific ligand (mannose 6-phosphate). The experimental basis of this research is important and is set out elsewhere in this article (see section 'Functional Complementation of Lysosomal Diseases').

Action myoclonus-renal failure syndrome

Action myoclonus-renal failure syndrome (AMRF) is a distinctive form of progressive myoclonic epilepsy associated with renal failure. It has some biochemical features of Gaucher disease but unlike I-cell disease, affects targeting of nascent β -glucocerebrosidase to the lysosome that is independent of the mannose 6-phosphate ligand (Berkovic *et al.*, 2008). In AMRF, if the renal failure occurs, it is rapidly fatal with focal glomerulosclerosis and features of collapsing glomerulopathy; marked protein loss (nephrotic syndrome) may be present. Some patients develop dementia and peripheral neuropathy; neuropathological examination has showed accumulation of irregular and refractile autofluorescent pigmented granules in non-neuronal cells in the cerebral cortex, globus pallidus, and the cerebellum.

This unique disease is caused by mutations in the SCARB2 gene otherwise known as the gene encoding lysosomal intrinsic membrane protein (LIMP-2). This is another critical lysosomal membrane component, now known to be the chaperone molecule that brings about the 'mannose 6-phosphate-independent'

trafficking of nascent β -glucocerebrosidase to the lysosome (Reczek *et al.*, 2007). Patients with mutations in the LIMP-2 gene develop a clinical syndrome that was not predicted by knowledge of the molecular defect. Assays of fibroblasts obtained from patients show diminished ($\approx 10\%$) residual acid β -glucosidase due to lysosomal glucosylceramidase activity with an abnormal glycosylation pattern, suggesting reduced abundance of post-Golgi forms of the enzyme. However, leukocytes show acid β -glucosidase activity within the healthy reference range. Thus the condition is remarkable in that the deficiency of LIMP-2 function leads to a mosaic biochemical phenotype with normal activity of acid glucocerebrosidase due to satisfactory targeting to the lysosome in macrophages and leukocytes, but a deficiency of acid β -glucosidase activity in fibroblasts and other somatic cells in which LIMP-2 particularly exerts its chaperone rôle for delivery of nascent glucocerebrosidase to its lysosomal destination.

Deficiency of an Activator Protein

Sphingolipid activator proteins

Several proteins have been recognized as key accessories to the action of lysosomal proteins, and when deficient as a result of genetic mutation usually lead to loss of function affecting multiple systems (Kolter and Sandhoff, 2005).

In this category are deficiencies of sphingolipid activator proteins, which are cleaved products of a single gene (SAP). Each activator has distinct functions based on the activities of the discrete polypeptides, saposins A–D. Generally, inherited defects of saposins lead to complex disorders with functional deficiency of one or more lysosomal hydrolases toward their natural but not usually their artificial substrates – thus often leading to difficulties in diagnosis based on conventional biochemical assays in general use. For example, deficiency of Sap C usually leads to a complex syndrome in infants with features of metachromatic leukodystrophy and Gaucher disease due to loss of the ability of the saposin to present substrates (glucosylceramide and sulfatide) to β -glucosylceramidase and arylsulfatase A, respectively. Rare cases of saposin C deficiency have been associated with an attenuated juvenile form of Gaucher disease, without overt features of ‘metachromatic leukodystrophy.’ In these patients, administration of exogenous enzyme is unlikely to be beneficial because the activator protein is critical for its catalytic function. It is also notable that activity of acid β -glucosidase or arylsulfatase A (determined with fluorogenic or chromogenic substrates) is not deficient, even though many pathological features of disease are present and tissue biopsy specimens (and urine samples in the case of sulfatide) reveal characteristic lysosomal storage of sphingolipid.

The single-chain polypeptide, GM2 activator protein, plays a critical rôle in presenting membrane-bound ganglioside substrate to hexosaminidase A; GM2 activator and the heterodimeric hexosaminidase A are absolutely required for breakdown of this complex sphingolipid substrate. Very rare mutations in GM2 activator cause a disease that is clinically indistinguishable from late-infantile Tay-Sachs disease but, again, without any deficiency of hexosaminidases toward the fluorogenic substrates in routine diagnostic use. Moreover, other rare variants of Tay-Sachs disease, first identified within an Hispanic population, occur without apparent deficiency of

hexosaminidase A but with a mutation (R288H) in the HEXA gene rather than the GM2 activator gene: in this case, the single amino acid change in the α -subunit of hexosaminidase abrogates binding to the GM2 activator protein. Based on conventional biochemical testing, hexosaminidase activity toward artificial fluorogenic substrates is unremarkable, but the activity toward the natural GM2 substrate is impaired.

Intensive biochemical and genetic studies of a severe and disabling condition known as ‘multiple sulfatase deficiency,’ revealed the presence of a unique modifying factor, sulfatase modifying factor (SUMF). When SUMF is inactivated, deficiencies of numerous sulfatases occur in association with features of MPS, dry scaly skin (ichthyosis), and leukodystrophy (Sardiello *et al.*, 2005). The factor is an enzyme located on the endoplasmic reticulum that serves to modify all sulfatases present in mammals, thereby activating them. For enzymatic activity, a conserved cysteine residue present in a short peptide sequence in all eukaryotic sulfatases must be oxidized to formylglycine – a critical posttranslational modification. Patients with multiple sulfatase deficiency and harboring two inactivating mutations in the human SUMF gene have a variable phenotype with multiple deficiencies – including the numerous sulfatase activities implicated in sequential degradation and turnover of the many highly sulfated glycosaminoglycans. Neurological disease due to arylsulfatase A deficiency with features of metachromatic leukodystrophy and extensive demyelination is usually present; deficiency of steroid sulfatase appears to account for the ichthyosis.

Galactosialidosis

This monogenic disease is ultimately caused by deficient activity of three lysosomal acid hydrolases that are assembled into a stable functional complex (Caciotti *et al.*, 2013). The clinical features are shared in part by Hurler disease (MPS I): coarse facies, vertebral changes and storage foam cells in the bone marrow with vacuolated lymphocytes, as well as cherry-red spots in the macular region of the retina and visceromegaly. However the patients are deficient in β -galactosidase and neuraminidase, leading to the accumulation of sialyl oligosaccharides and glycopeptides in fluids and connective tissues. Mutations in the gene encoding what has come to be known as protective protein, otherwise designated cathepsin A, are responsible for galactosialidosis. The condition arises because the mutated protein, a serine carboxypeptidase, is unable to carry out its normal function by binding to β -galactosidase and neuraminidase, which would assure the physiological trafficking of the two newly formed glycosidases to the lysosome in a stable multi-enzyme complex.

Deficiency of a Lysosomal Membrane Protein or Transporter

Mutations in genes encoding this class of lysosomal proteins have been identified in several disorders and have proved scientifically informative (Mancini *et al.*, 2000).

Several of these defects show preferential expression in lysosome-related organelles of specialized cells and illustrative examples are provided in Section ‘Defects in the Biogenesis and Function of Lysosome-Related Organelles.’

Cystinosis

Cystinosis is one of the first lysosomal disorders to be accessed by a specific treatment (Nesterova and Gahl, 2013). The disease is a transport defect which causes systemic disease typified by the early development of renal tubular acidosis, with salt wasting and a Fanconi syndrome characterized by amino aciduria, phosphaturia, and glycosuria. Premature rickets and skeletal demineralization with episodes of dehydration and salt-wasting are followed by full-blown renal failure; thyroid failure, heart disease, and deposits of cysteine in the cornea, leading to impaired vision, are other characteristics. Patients with cystinosis usually require renal transplantation and other supportive measures, but the introduction of the aminothiols agent, cysteamine, to remove by complexation the accumulated intra-lysosomal cysteine is a crucial measure for delaying the advance of multisystem failure. Topical use of cysteamine has a notable effect on cystine crystals in the cornea and pre-empts the inflammation which causes ulceration effectively preserves vision. Cystinosis is due to mutations in CTNS encoding the transporter, cystosin, an integral protein of the lysosomal membrane; the disease arises as a result of a failure of the lysosome to export the products of intra-lysosomal proteolysis – cystine is formed from the oxidative dimerization of cysteine and as a result, non-protein free cystine accumulates in the lysosomes.

Clinically distinct inborn defects of lysosomal transport include the very rare ‘Salla disease,’ principally confined to persons of Finno-Ugric ancestry, in which free sialic and glucuronic acid accumulate in the lysosomal compartment due to a failure of egress after release from the breakdown of glycosaminoglycans and sialoglycoprotein digestion. The manifestations include hypotonia, cerebellar ataxia, and dementia; coarse features and enlargement of the liver and spleen occur with distended lysosomes identified by ultrastructural studies of tissue samples. Large amounts of free sialic acid is excreted in urine and a H⁺/anionic sugar symporter system for sialic acid and glucuronic acid export is impaired due to mutations in SLC17A5, encoding a protein (sialin), with a transport function typical of a family of anion/cation symporters.

There is also a very uncommon ‘cobalamin transport disorder,’ leading to intracellular deficiency of both active methyl- and adenosylcobalamin cofactors; this is classified as a cblF defect and has been shown to be due to mutations in the human LMBRD1 gene. The cognate lysosomal membrane protein apparently exports free cobalamins released by digestion of the transcobalamin II-receptor complex after internalization and transfer to the lysosomal compartment. Recently, genetic investigations into rare patients with a phenocopy of the cblF defect, have identified another cause of failure to release vitamin B12 from lysosomes: causal mutations in ABCD4, a gene that encodes an ABC transporter, have been identified (Coelho *et al.*, 2012). These genetic studies shed new light on the physiology of cobalamin metabolism, since ABCD4 was previously considered to be expressed on the peroxisomal membrane. Studies in fibroblasts from patients and healthy individuals show that ABCD4 co-localizes with the lysosomal proteins LAMP1 and LMBD1, the latter being deficient in the cblF defect. Since mutations affecting the putative ATPase domain of ABCD4 impair function, it seems likely that ATPase activity is a functional requirement for

cobalamin release during intracellular processing of vitamin B12.

Danon disease

Danon disease represents another lysosomal membrane defect not directly involving transporter activity, but LAMP-2, a protein, mapping to the X-chromosome and implicated in the control and activation of macro-autophagy. As a large highly glycosylated integral membrane glycoprotein, LAMP-2 serves a critical coordinating function between housekeeping lysosomal digestion and the disposal of large engulfed particles after formation of autophagic vacuoles – processes linked to cellular nutrient-sensing. LAMP-2 deficiency in Danon disease has principal effects in cardiac muscle, neurons, and skeletal muscle, tissues in which the constituent cells are particularly active in autophagy.

Defects in the Biogenesis and Function of Lysosome-Related Organelles

Abnormal biogenesis of lysosomes is illustrated by Hermansky–Pudlak diseases (Type 1–9); Chédiak–Higashi disease and the Griscelli syndromes Types I–III

The Hermansky–Pudlak syndrome describes a group of instructive conditions caused by genetic defects of lysosome-related organelles – these have far-reaching effects in the patient but also inform understanding of the biogenesis and specialized functions of several critical cellular constituents.

Lysosome-related organelles are found principally in specialized cell populations in which they serve to store and secrete proteins required for specific functions, for example, the platelet, the melanocyte, and T-lymphocyte (Luzio *et al.*, 2014). Diseases affecting lysosomal biogenesis and the formation of lysosome-related organelles point to essential functions of genes hitherto not recognized, but which have crucial rôles in pigmentation, innate and adaptive immunity, as well as blood coagulation; they provide, if it were needed, further examples of the debt of molecular cell science to the study of human disease. It appears that organelles such as the melanosome interact physically with mitochondria, endoplasmic reticulum at specific membrane-contact sites during biogenesis – a process mediated by mitofusin 2, a fibrillary protein which allows lipid transfer and regulates Ca²⁺ fluxes that affect membrane dynamics as well as their size, shape and motility (Daniele *et al.*, 2014).

Hermansky–Pudlak and Chédiak–Higashi syndromes are autosomal recessive conditions typically associated with oculo-cutaneous albinism and defective hemostatic function due to deficiency of the storage pool of coagulation factors in the dense δ granules of the blood platelet (Huizing *et al.*, 2008; Seward and Gahl, 2013; Introne *et al.*, 2015).

These diseases disturb the function of intracellular vesicles that are related to lysosomes, including the platelet dense body (containing serotonin, ADP and other nucleotides as well as Ca²⁺ ions) and the melanosome, in which melanin pigment is packaged. Hermansky–Pudlak syndrome appears to be a disorder of vesicle formation and components of an adaptor complex responsible for fashioning the structures from the trans-Golgi network.

Chédiak–Higashi syndrome is associated with defects in vesicle trafficking of critical intracellular cargo mediated by GTPase activity; in this condition, the *LYST* (lysosomal trafficking regulator gene), which encodes a large protein of ill-understood function, is mutated. Chédiak–Higashi syndrome causes not only albinism, but severe immunodeficiency and mild bleeding; abnormal inclusions in white blood cells and deficiency of platelet-dense bodies are associated with a mild bleeding tendency and recurrent bacterial, and occasionally viral or fungal infections. These microbial infections, which may be severe, typically affect the skin and respiratory tract. By the time they reach adult life, patients develop neurological symptoms affecting peripheral nerves, the extrapyramidal system, and cerebellum. Also, most of the patients enter an accelerated phase of lymphoproliferation which, without the availability of pre-emptive hematopoietic stem-cell transplantation, usually proves fatal – in a syndrome of hemophagocytic lymphohistiocytosis.

Hermansky–Pudlak syndrome occurs in nine distinct genetic forms, and although the function of those other than the adaptor protein AP-3 B1 are not thoroughly understood, these gene products interact in the biogenesis of lysosome-related organelle complexes. In the case of Hermansky–Pudlak syndrome, abnormal δ granules in the platelets and secretory granules in T-cells, as well as the lamellar bodies in Type II alveolar cells are found. Hermansky–Pudlak syndrome is characterized by a marked bleeding diathesis, particularly after surgery (Seward and Gahl, 2013). The albinism requires careful management to reduce the risk of light-induced cancers. In some of the variants, progressive pulmonary fibrosis occurs to the extent that lung transplantation may be required as a life-saving measure. Infections occur as a result of defective granulocyte function of peripheral white blood cells.

Related Conditions Affecting Organelle Biogenesis

Griscelli syndromes (Types 1–3) are also associated with albinism and immune deficiency: in Type 1, cognitive impairment and neurological function are frequent. In Griscelli syndrome Type 2, episodes of disseminated uncontrolled phagocytosis with gross hemolysis and fever develop due to uncontrolled activation of macrophages and T-lymphocytes, with widespread infiltration of lymph nodes and visceral organ as a result of unregulated natural-killer T-cell function. Griscelli syndrome occurs in three genetically distinct variants: Types 1 and 2 are caused by mutations in genes that localize to the same region of chromosome 15q (*Myosin-5a* and *RAB27a* genes) encoding proteins which bring about vesicular transport, especially exocytosis of cytotoxic granules (Krzewski and Coligan, 2012). Griscelli syndrome Type 3 is caused by mutations in *MLPH* – a gene that encodes melanophilin, a protein that complexes with Rab 27a and myosin Va implicated in the transport of melanosomes. The most severe of these syndromes is Type 2 Griscelli syndrome where the hemophagocytic crisis often proves fatal unless hematopoietic stem-cell transplantation is undertaken.

Lysosome-Related Organelles and the Osteoclast

As noted, lysosomal-related organelles participate in functions that are external to the cell. The modeling of bone is brought

about by specialized cells of mononuclear-phagocyte origin, termed osteoclasts. Digestion of mineralized osteoid occurs as this population of modified scavenger cells continuously digests bone matrix – a key function in the repair of fractures as well as maintenance of skeletal strength and integrity throughout life. The specialized sealing zone which encloses the ruffled cell border of the osteoclast, the so-called resorptive lacuna, is in effect a multi-exteriorized space formed by lysosomal fusion. The subcellular compartment is acidified through the action of the vacuolar V-(H⁺)-ATPase and mediated by the chloride conductance channel, *CLCN7*, which stabilizes the chemiosmotic gradient within the closed environment of the lacuna.

Failure to acidify this sub-osteoclastic resorptive vacuole as a result of mutations in the lysosomal V-(H⁺)-ATPase impairs diverse resorptive functions; this leads to formation of dense, un-remodeled bones ('osteopetrosis') (Frattoni *et al.*, 2000). Mutations in the gene, *CLCN7*, encoding the lysosomal chloride channel expressed on the lysosomal membrane but, in the adapted exteriorized lysosomal compartment of the osteoclast, on the ruffled border, also cause human osteopetrosis – as a result of failed acidification in the subcellular vacuole. This verifies the key function of the chloride counterion transporter in osteoclast activity (Kornak *et al.*, 2001). Mutations in cathepsin K, an acid hydrolase expressed by the osteoclast with selective activity toward collagen, elastin, and gelatin in cartilaginous and bone matrix, also impair bone modeling and cause a variant of osteopetrosis – 'osteopycnodysostosis' (Gelb *et al.*, 1996). This hereditary disorder describes mis-shaped hyper-dense bones associated with dwarfism.

Beyond their rôle in digestion, there are examples illustrated by diseases of specific function of lysosomal components in other specialized cells. In cells that contribute to immune function, and myeloid lineage shared with the osteoclast, a rare inherited deficiency of the iron-containing type 5 purple acid phosphatase (*Acp5*) has far-reaching effects. This lysosomal protein is a di-iron enzyme that is highly expressed in osteoclasts and, widely termed 'tartrate-resistant acid phosphatase (TRAP)', has long been used as an osteoclast 'marker' in histochemical studies. Type 5 acid phosphatase is also abundantly expressed in other cells of the mononuclear phagocytic phenotype, including dendritic cells and Langerhans cells in the dermis. The enzyme dephosphorylates the skeletal sialoprotein, osteopontin – thereby attracting attachment of osteoclasts to bone matrix where it also stimulates formation of their ruffled borders at the resorptive interface.

However, the pervasive function of this lysosomal protein has been revealed by studies of informative mutants informed by characterization of mice in which the gene has been mutated. Mutations in *ACP5* are responsible for a recessively inherited immuno-osseous dysplasia, 'spondyloenchondrodysplasia,' in mice and humans (Briggs *et al.*, 2011). Spondyloenchondrodysplasia affects ossification and bone modeling in vertebrae and long bones, causing short stature; in addition, the immune system is dysregulated with the development of autoimmunity, including systemic lupus erythematosus and Sjögren's syndrome. These disparate phenomena are in part explained by the accessory rôle of the soluble phosphorylated isoform of osteopontin as an early

T-lymphocyte activation factor (ETA-1) with effects on integrin binding that influence expression of other immuno-regulatory cytokines such as IL-10 and IL-12 (Bune *et al.*, 2001).

Functional Complementation of Lysosomal Diseases

In 1967, Elizabeth Neufeld, then working at the National Institutes of Health in Bethesda, USA, was aware that meta-chromatic deposits in the fibroblasts indicated the accumulation of glycosaminoglycans; at the time intrigued by the biosynthesis of uronic acids, she investigated fibroblasts cultured from skin biopsies obtained from patients with Hurler syndrome (MPS I). Excessive formation of glycosaminoglycans could not be demonstrated and thus with Joseph Fratantoni, Neufeld studied the incorporation of ^{35}S -labeled sulfate into TCA-insoluble material. In contrast to healthy fibroblasts, where the incorporation of sulfate leveled off after a few hours, radioactive incorporation into the glycosaminoglycans precipitated from the fibroblasts of a Hurler patient, continued to increase linearly over several days of culture. Similar behavior occurred in the clinically similar but genetically distinct (X-linked) condition, Hunter disease (MPS II). By accident, Hunter and Hurler cells were combined and, unexpectedly, sulfated glycosaminoglycan accumulated normally in the mixed culture; after pre-labeling with radioactive sulfate, the rate of degradation (retarded, as expected, in cells from patients with MPS syndromes), was restored to that observed in fibroblasts from healthy subjects (Fratantoni *et al.*, 1968). Eventually Neufeld and colleagues showed that a factor in the medium, later called a 'corrective factor,' was secreted from the diseased fibroblasts mutually to complement the degradative defects in fibroblasts obtained from patients with genetically and clinically distinct syndromes belonging to discrete complementation groups (Fratantoni *et al.*, 1969). In collaboration with Dr. Victor McKusick, and thus informed by scrupulously characterized biopsy subjects, Neufeld and colleagues defined specific corrective factors for MPSI, MPSII (Hunter and Hurler syndromes) and different complementation groups in Sanfilippo syndromes (MPS III, Sanfilippo A and B), as well as Maroteaux-Lamy disease (MPS VI) (Neufeld, 2011).

Investigations by William Sly and colleagues in St Louis showed that acid β -glucuronidase deficiency in fibroblasts obtained from patients with a cognate mucopolysaccharidosis (MPS VII – Sly syndrome) could be corrected by supplying the enzyme exogenously in the medium of the culture. Later Sly, shortly followed by Neufeld, Shapiro, and others, found that a particular high-molecular weight (phosphohexosyl) form of the respectively deficient enzyme, released into the medium from cultured fibroblasts, possessed the complementing property for therapeutic correction, *in vitro*. Eventually, Sly and colleagues showed that the structural feature required for saturable uptake (of acid β -glucuronidase), was mannose 6-phosphate – a carbohydrate modification previously unknown in mammalian cells (Natowicz *et al.*, 1979). The general applicability of this phenomenon was confirmed by Neufeld and colleagues who showed that excess mannose 6-phosphate in the medium inhibited the uptake of complementing α -L-iduronidase, the enzyme activity deficient in MPS I (Hurler disease).

I-Cell Disease

Leroy and DeMars also in CE 1967 reported striking abnormalities in fibroblasts cultured from patients suffering from a very rare condition with combined clinico-pathological features of a sphingolipidosis and mucopolysaccharide disorder – the condition was named inclusion-cell disease (I-cell disease) but its other name is mucopolipidosis (on the basis of clinical and genetic criteria, now sub-classified into types II and III). While the cells and tissues of the patient showed numerous deficiencies of lysosomal acid hydrolases and abundant lysosomal storage of glycosaminoglycans and sphingolipids, high activities of these enzymes (up to 20-fold greater) than healthy reference values could be detected in plasma and urine. Indeed, this behavior was mimicked by I-cell fibroblasts in culture: they remained intrinsically deficient with a 'storage' phenotype but released many enzymatically active acid hydrolases into the medium (Leroy and DeMars, 1967).

A decisive finding, in the 1970s however, was that complementation studies as first pioneered by Elizabeth Neufeld and colleagues showed that the acid hydrolases now present in excess in the medium were able neither to complement I-cell fibroblasts nor fibroblasts cultured from patients with various mucopolysaccharidoses. Hickman and Neufeld also made the critical observation that I-cell fibroblasts were capable of taking up acid hydrolases secreted into culture medium by healthy fibroblasts – leading to biochemical complementation. The findings suggested that lysosomal enzymes contain a recognition marker for uptake and transport to lysosomes; fibroblasts from patients with I-cell disease, which secrete abundant lysosomal acid hydrolase into the medium, are unable to generate the appropriate ligand (Hickman and Neufeld, 1972). This explanation was definitively confirmed in molecular terms by William Sly and colleagues with the identification of mannose 6-phosphate as the principal recognition moiety (Natowicz *et al.*, 1979). The conceptual insight that, as a result of intracellular mis-sorting, the enzymes were not trafficked to their lysosomal destination, led to the identification of a default pathway allowing active egress to the medium. Careful radio-tracer studies showed that numerous secreted lysosomal glycoproteins had escaped phosphorylation during passage through the *trans* Golgi system but were nonetheless actively transported to the plasma membrane and released. In contrast, cells from patients without I-cell disease synthesize acid hydrolases destined for the lysosome which harbor the mannose 6-phosphate (M6P) recognition signal; this is incorporated within oligosaccharide moieties as the nascent polypeptides traverse the Golgi network, there undergoing further posttranslational processing with acquisition and unmasking of the appropriate ligand – which is retained for intracellular sorting and delivery to the lysosomal compartment. This sorting pathway for newly formed acid hydrolases destined for the lysosomal matrix is not absolute, it is 'leaky.' About 15% of the complement of nascent enzymes generated by human cells in culture is directed to the plasma membrane and is released into the medium – from which it can be taken up after binding to other cell-surface M6P receptors. The so-called secretion-reuptake pathway appears not to be significant for most lysosomal hydrolases under healthy conditions *in vivo*.

Subsequent research by Stuart Kornfeld and Kurt Von Figura and their colleagues respectively in the US and Germany led to the characterization of mannose 6-phosphate receptors on the plasma membrane and of two intracellular enzyme complexes that catalyze formation of the mannose 6-phosphate recognition marker – UDP-*N*-acetylglucosamine: glycoprotein *N*-acetyl glucosamine-1 phosphotransferase and the second ('unmasking') enzyme, *N*-acetylglucosamine phosphoglycosidase (von Figura and Hasilik, 1986; Kornfeld, 1987). Patients with I-cell disease are deficient in the activity of the phosphotransferase – a multi-subunit polypeptide complex encoded by two genes. It is worth noting that in I-cell disease, the lysosomes in some tissues, such as the liver, certain macrophage populations, kidney, and brain have a near-normal complement of acid hydrolases although all are deficient in phosphotransferase activity, implying that distinct pathways for sorting the nascent hydrolases to the lysosomal compartment is used preferentially in some cell types and mannose 6-phosphate is not the only signal for delivery to lysosomes. Further, the tartrate-sensitive lysosomal acid phosphatase isozyme, Acp2, and β -glucocerebrosidase (deficient in Gaucher disease), do not employ the M6P signal (Reczek *et al.*, 2007). In Acp2, an exposed tyrosine residue signal in the cytoplasmic tail of this membrane polypeptide directs the nascent enzyme to the lysosome. Here in cooperation with the purple acid phosphatase, Acp5 (TRAP), the acid phosphatase has been shown to catalyze removal of the phosphate moiety from the M6P-linked glycoprotein hydrolases within the lysosomal matrix space (Makrypidi *et al.*, 2012). The mannose 6-phosphate-independent mechanism for targeting β -glucocerebrosidase to the lysosome, at least in some tissues, involves the membrane glycoprotein LIMP2 which serves a specific chaperone molecule. It now appears that there are several mannose 6-phosphate-independent pathways, some of which are not fully characterized (Kornfeld, 1987); it is nonetheless unclear as to why more than one sorting pathway is needed for lysosomal biogenesis.

Lysosomal Complementation *In Vivo*

The mannose 6-phosphate receptor system (cation-independent mannose 6-phosphate/insulin-like growth factor II receptor) system proved to be functionally 'leaky' *in vivo* – thus allowing a fraction of nascent lysosomal proteins to be released from cells, later to be taken up by cell surface receptors of other cells present in tissues at a distance. The term, 'secretion-recapture,' has been coined for this constitutive process.

Beyond experiments with cultured cells *in vitro*, clinical observation supports the concept of secretion-recapture for functional complementation of genetic defects of the lysosome. While most lysosomal diseases are inherited as autosomal recessive traits, three informative disorders are transmitted on the X chromosome – Hunter syndrome (MPS II, caused by mutations in the α -iduronate sulfatase gene), Anderson-Fabry disease (caused by mutations in the acid α -galactosidase A gene), and Danon disease (mutations in LAMP-2, lysosomal-associated membrane protein-2). Female heterozygotes with Danon disease are invariably symptomatic; however, unless unusual events have occurred on the X chromosome, with skewed Lyonization, female heterozygotes for MPS II do not show signs of this disease. Since, as a result of Lyonization, human females are

mosaics for their respective parental X chromosomes, this shows that secretion-recapture of appropriate molecular forms of iduronate sulfatase, which is deficient in affected males with Hunter disease, can be complemented *in vivo* by cells expressing the wild-type parental allele. While intercellular complementation of defective lysosomal membrane function *in vivo* will not readily occur, it is unclear why female heterozygotes for Fabry disease are symptomatic, although plasma, as opposed to tissue glycoforms of acid α -galactosidase A, are not readily taken up by human fibroblasts – a speculative possibility is that in this instance, inactivation of the requisite recognition marker occurs in the circulation. While the investigations of several informative human inherited disorders of lysosomal function have been very revealing for understanding the function of lysosomes and the nature of their biogenesis within the living cell, the laboratories of Elizabeth Neufeld and William Sly proved in the end not to be the first to deliver effective therapy involving enzymatic augmentation for lysosomal diseases (see Gaucher disease).

Treatment of Lysosomal Diseases

All these developments are predicated on careful experiments that show the central rôle of the lysosome in the cell and its critical functions in reclaiming and recycling of macromolecular constituents in metabolic homeostasis and are reviewed elsewhere (Cox, 2015).

Therapeutic stratagems specifically for lysosomal disease include:

- a. Dissolution and removal of intralysosomal storage material
- b. Enhanced exocytosis of pathological intralysosomal content
- c. Modulating substrate biosynthesis (substrate-reduction therapy)
- d. Complementation stratagems
 - i. Hematopoietic stem-cell (previously bone-marrow) allo-transplantation
 - ii. Reinfusion of vector-transduced autologous hematopoietic stem cells
 - iii. Direct gene transfer
 - iv. Enzymatic augmentation.

Dissolution and Removal of Intralysosomal Storage Material

Cystinosis

This condition is caused by genetic defects in the lysosomal cysteine/proton symporter, cystinosin. Systemic accumulation of the oxidized sulfamino acid causes widespread injury, particularly in the renal tubule, and also to the thyroid, heart, and other tissues related to the presence of crystalline aggregates of oxidized cystine dimers. A successful and simple biochemical approach to the matter of this storage has been long adopted and the aminothiol, cysteamine which interacts with the aggregates is capable of converting cystine to a mixed disulfide of cysteine-cysteamine which can leave the lysosomal via a cationic amino acid transporter system, which also transports the basic amino acid, lysine. If high doses of cysteamine are given early in the disease, there is a significant delay of progression to renal failure and topical therapy with this aminothiol can

prevent loss of vision and painful damage to the cornea due to local cystine (Nesterova and Gahl, 2013). This therapeutic approach, not only of clinical importance, shows that under some circumstances, the simple presence of excess material within the lysosomal compartment (crystalline cystine) is a credible therapeutic target, and moreover, a verifiable basis for the ensuing pathology and lysosomal dysfunction.

Niemann–Pick disease type C

Niemann–Pick disease Type C, is due to mutations in genes encoding cognate proteins (NPC1 and NPC2) that collaborate to bring about the egress of free cholesterol and other lipid molecules from the endolysosomal system. Experimental work in Niemann–Pick Type C in mice and cats shows that cyclodextrins, which are cyclic oligosaccharides with amphipathic properties when given intravenously have beneficial effects. Intrathecal cyclodextrin may cause deafness, but clears intracellular cholesterol that accumulates in Niemann–Pick disease Type C, prevents the onset of the phenotype in mice and cats – currently, and with high expectation of clinical benefit, this drug is currently undergoing Phase 1 and Phase 2 studies in human patients with NPC.

Enhanced Exocytosis of Pathological Intralysosomal Content

A further method directly to mitigate the effects of lysosomal storage is based on stimulating exocytosis and trials are underway in Niemann–Pick disease Type C. Experimental studies in several lysosomal disease models in which expression of heat-shock proteins that serve as molecular chaperones by exposure to the hydroxylamine co-inducer of the heat-shock response (arimoclomol) appears to be beneficial. Now licensed to the company Orphazyme, this agent is in clinical investigation for Niemann–Pick disease Type C – the results of this bold initiative are awaited, but promise an improved understanding of the rôle of excess lysosomal content in pathogenesis in this disease.

Experimentally enhanced TFEB activity in cell models of multiple sulfatase deficiency and Pompe disease rapidly induced exocytosis of lysosomal storage contents. Preliminary results showing glycogen clearance in muscles of mice that model Pompe disease reported by the Ballabio laboratory suggest that manipulation of the transcriptional control network for lysosomal biogenesis and autophagy through the TFEB may justify further clinical experimentation. However, since TFEB has been implicated in renal and other human cancers, therapeutic manipulation of its expression will clearly require cautious exploration.

Modulating Substrate Biosynthesis (Substrate-Reduction Therapy)

Understanding the biochemical pathology of metabolic diseases has a productive history in therapeutic development. Hypercholesterolaemia, hereditary tyrosinemia, and gout are metabolic disorders readily identified as over-production diseases due to the inability satisfactorily to degrade toxic metabolites. In the case of the sphingolipidoses, which are an important group of lysosomal diseases the identification of

inhibitors of biosynthesis has led recently to productive clinical experimentation. The stratagem remains under clinical development in Fabry disease, chronic neuronopathic Gaucher disease, and glycosphingolipidosis such as Niemann–Pick disease Type C and GM2 gangliosidosis. Early success in this field is also stimulating investment to discover tractable inhibitors to rebalance disordered glycosaminoglycan metabolism in the mucopolysaccharidoses. In the case of small molecules that may be chosen as selective inhibitors of biosynthetic processes, it is more likely that an orally active inhibitory molecule can be obtained with the required specificity, as well as the capacity directly to traverse the blood–brain barrier and exert its effect in intractable neurological diseases.

The pharmaceutical use of inhibitors of biosynthesis is most often successful when the target is an early committed step critical for the formation of the toxic products. In the case of the sphingolipid molecules, there are numerous critical functions: ceramides stimulate apoptosis and inhibit cell growth, as well as differentiation. At the same time, the chemically related sphingoid bases stimulate proliferation and control inflammatory processes, as well as the migration of cells. However, both nitisinone and the statin drugs prove to be highly successful agents in medical use, since they attenuate, rather than abrogate, the biosynthesis of the essential precursors in hereditary tyrosinemia type 1 and hypercholesterolaemia, respectively. Early success in this approach has occurred in Gaucher disease, a sphingolipidosis, where the putative toxins accumulate in the face of the lysosomal deficiency acid β -glucosidase are the many variant *N*-acyl-sphingosyl-1-*O*- β -D glucosides with differing acyl and sphingosine moieties, as well as their unacylated congenors, the glucosylsphingosines. In the adult-onset, and therefore milder clinical forms of Gaucher disease, β -glucosylceramides are derived from exogenous membrane components, particularly during the phagocytosis of blood cells by macrophages. Lysosomal recycling of these cellular glycosphingolipids is limiting, but where the genetic defect is more severe, in cells such as neurons, high rates of endogenous turnover of glycosphingolipids in ganglioside-rich neurones are associated with neurological injury.

Currently, two main classes of inhibitor have been explored therapeutically for the treatment of the sphingolipidoses. The target enzymatic reaction is catalyzed by UDP-glucosylceramide transferase, which leads to the formation of β -glucosylceramide that accumulates in Gaucher disease. This glycosphingolipid serves as a scaffold for the synthesis of higher-order glycosphingolipids, such as globosides and gangliosides. An acylated iminosugar, *N*-butyldeoxynojirimycin, first previously explored for an unrelated application in the control of human immunodeficiency virus, was chosen for clinical development in the sphingolipid disorders, including Gaucher disease, by the author working with FM Platt and T Butters in the University of Oxford. *N*-butyldeoxynojirimycin inhibits the biosynthesis of glucosylceramide in cultures of murine macrophages and in animals with the gangliosidosis, Sandhoff disease lacking β -hexosaminidases A and B, the agent decreases accumulation of GM2 ganglioside in the brain thereby increasing survival. Having already been administered to humans as a potential

inhibitor of the viral α -mannosidases required for the synthesis of the HIV coat glycoprotein, the drug was re-purposed for trial in Gaucher disease. It was found to have a modest therapeutic effect, reducing visceral enlargement and slowly improving hematological parameters, as well as macrophage molecules such as the enzyme chitotriosidase, which is a biomarker of the macrophage effects of Gaucher disease. Miglustat ultimately gained a license and was approved as a second-line agent for Gaucher disease in patients unable to tolerate or receive intravenous infusions of corrective enzyme. Miglustat has drawbacks, however, and although an already available small molecule it has many unwanted effects, for example on intestinal disaccharidases, thus inducing abdominal symptoms.

The iminosugar, designated miglustat, was able to enter the brain and was later shown to have modest effects on some clinical manifestations in patients with Niemann–Pick disease Type C, for which it has also been approved and is the only currently available drug for this neurodegenerative disease. While other congeners of the approved iminosugar for a lysosomal disease are in development, miglustat has not found great favor internationally, mainly because of its unwanted gastrointestinal effects. However, the ostensible success of the agent shortly after launching had a signal effect in stimulating further investment and competitive interest. Scientifically this was based on longstanding research by Norman Radin and his junior colleague James Shayman of the University of Michigan, Ann Arbor. This group pioneered the chemical development of inhibitors based on a ceramide structure, which unlike miglustat eventually led to the development of congeners that were potent highly specific inhibitors of UDP glucosylceramide with a K_i of approximately 25 nM. The lead agent appears to be a transition-state analogue and remain orally active, although it does not enter the brain. After 15 years of developmental work and several trials spanning many years, the final compound, termed eliglustat, has been approved for first-line oral use in adults with Type 1 Gaucher disease. Eliglustat has been reported to have salutary effects that resemble the efficacy recorded in naïve patients treated with enzyme therapy. The drug was found to be non-inferior in 2-year studies of approximately 160 patients worldwide who had previously been stabilized on imiglucerase enzyme therapy; more than 400 patients have now been exposed to the drug worldwide.

The burgeoning success of this developmental program, which required major investment from the Genzyme company, has led to further developments and the filing of a patent for chemically novel UDP-glucosylceramide transferase inhibitors that may be used in a range of metabolic conditions. Their particular interest for therapeutic evaluation will be particularly those devastating neurodegenerative disorders of sphingolipid metabolism which affect the brain including those which impair lysosomal recycling of glycosphingolipid constituents in neural cell membranes. Genzyme, now a Sanofi company, has obtained an innovative lead molecule that is chemically distinct from the prototypic inhibitors first developed by Radin, Shayman, and their colleagues. The entirely novel compound, which appears to have favorable biochemical and pharmacokinetic properties, is a high-affinity inhibitor, traverses the blood–brain barrier, and has been

tested on healthy human volunteers without ill effect. This in-house discovery program should allow the development of powerful agents to restrict formation of toxic sphingolipids and address the lexicon of disordered ganglioside and globoside metabolism, including systemic (as in Fabry disease) and central effects for example, for use in neuronopathic Gaucher disease and the GM2 gangliosidoses.

Hematopoietic Stem-Cell Transplantation

Hematopoietic stem-cell therapy was an early potentially curative treatment in lysosomal diseases; it was first applied in the treatment of mucopolysaccharidoses MPS I and II and, successful in 1982, for the severe systemic manifestations of Norrbottnian (chronic neuronopathic) Gaucher disease.

Hematopoietic stem-cell transplantation provides a complement of hematopoietic cells from the donor that are competent in metabolizing lysosomal substrates: in the case of Gaucher disease, in which pathological macrophages are a major component, safe and successful engraftment has the potential for systemic cure. In the mucopolysaccharide disorders, microglia and other cells of myeloid lineage which are competent in metabolizing glycosaminoglycans and may secrete active lysosomal hydrolases of donor origin which ultimately find their way to peripheral tissues and viscera. These may slowly replace the microglial cell complement in the brain to improve the capacity to remodel tissues in which glycosaminoglycans have accumulated.

Clearly, a minority of patients are suitable recipients for hematopoietic stem-cell transplantation from either HLA matched-unrelated or HLA-matched related donors, but the therapeutic position of the more severe variant of MPSI (Hurler disease) is moderately well-established to provide benefit in the first year or so of life. It is salutary to appreciate that the stem-cell transplantation does not cure the condition and is unable to reverse established brain injury, and most of the crippling skeletal manifestations.

Hematopoietic stem-cell transplantation has been used in attempts to treat lysosomal diseases with neurological effects since stem cells from suitable donors have the potential to generate progeny that can migrate in small numbers over time to the brain by traversing the physical blood–brain barrier. In the recipient's bone marrow and other niches, donor cells give rise to self-renewing blood cell lineages that are competent in autonomous functions (such as phagocytosis and other immune responses); in the brain they appear to migrate to regions of disease where they can participate in scavenging activity as healthy counterparts of the diseased microglia and other cells with impaired lysosomal function. In the case of disorders such as Krabbe disease, the Sanfilippo syndromes (MPS III A–D), as well as metachromatic leukodystrophy, the donor cells may also secrete relevant acid hydrolases to complement neighboring tissue via the secretion-recapture process.

Reported outcomes of transplantation in more than 60 European patients with lysosomal diseases, especially in Gaucher disease, indicate that timely replacement of the diseased macrophage population and complementation of other hematopoietic lineages may greatly improve the disease with

effective correction – or arrest – of systemic disease. Contemporary experience shows improved outcomes as well as tolerance and safety of the procedure but for Gaucher disease, with the advent of three approved and safe enzyme infusion therapies, as well as orally active substrate biosynthesis inhibitors, hematopoietic stem-cell transplantation has restricted use – except in resource-poor countries where a one-off procedure may be preferred on the grounds of practicality and lifetime expenditure for treatment. At present, while hematopoietic stem-cell therapy offers the prospect of benefit in several disorders, particularly the mucopolysaccharidoses and possibly in severe chronic neuronopathic Gaucher disease (type 3), practical limitations restrict its use. Typically, an ideal HLA-matched sibling donor is not available, and despite the best efforts of agencies to identify matched unrelated donors, confirmation of compatibility may be delayed beyond utility; in any event, the success of the procedure mandates early and accurate diagnosis of the disease in the potential recipient – a persistent challenge in all therapeutic settings for rare disorders. Use of umbilical cord blood donors as a rich source of unrelated donor stem cells for suitable recipients, as well as optimized conditioning and myeloablative techniques have nonetheless gradually improved outcomes for several lysosomal diseases with systemic manifestations. However, the results obtained in patients with progressive neurodegeneration are at best suboptimal and often very disappointing.

Despite these improvements, persistent morbidity and mortality ($\approx 10\%$) is associated with transplantation – leading to complex decision-making that seeks to balance the severity of the disease with likely or optimal therapeutic response. With the exception of Hurler disease (MPS1) hematopoietic stem-cell transplantation has usually been deferred in favor of enzyme therapy whenever this is available. However while enzyme therapy may improve engraftment, hematopoietic stem-cell transplantation improves the high incidence of neutralizing allo-antibodies observed in MPS I after pharmacological enzyme replacement therapy. Hematopoietic stem-cell therapy has been extended to the lysosomal diseases characterized by rapidly progressive white-matter neurodegeneration such as metachromatic leukodystrophy and Krabbe disease. Research in this demanding field of clinical practice seeks to ensure that indications for the intervention are matched to the stage of disease and predicted therapeutic response.

Enzymatic Complementation

Molecular therapy for Gaucher disease

Gaucher disease was the first lysosomal disease for which a definitive molecular therapy was developed. After more than two decades of study at the National Institutes of Health under the direction of R.O. Brady, it was found that the functional deficiency of β -glucocerebrosidase in the macrophages of the spleen, liver, and other organs could be corrected experimentally by supplying the exogenous enzyme protein in a form that allowed molecular targeting to the macrophage via the mannose receptor (Deegan and Cox, 2012). Unlike the mannose 6-phosphate receptor, identified through

contemporaneous studies as a key participant in the biogenesis and intracellular delivery of many lysosomal hydrolases to the lysosomal matrix, the avidity of the macrophage for protein ligands with terminal mannose residues, rather than the phosphohexosyl moiety, is high. Thus the critical discovery by P.D. Stahl and colleagues of the mannose receptor, which mediates the avid uptake of mannose-terminated glycoproteins in human alveolar macrophages (Stahl *et al.*, 1978) underpinned a large international therapeutic program. Subsequent *in vivo* studies using radio-labeled placental and recombinant human glucosylcerebrosidase in patients receiving enzyme therapy for Gaucher disease confirmed specific uptake and targeting of these agents – enzyme protein half-life was < 5 min after infusion with rapid and avid uptake in macrophage-rich viscera and sites of disease in the bone marrow (Mistry *et al.*, 1996).

Commercial development of this targeted enzyme therapy and introduction of the CE 1983 Orphan Drugs Act in the United States was fortuitous: efficacy of the first placental-derived acid β -glucocerebrosidase remodeled to expose critical mannose residues for uptake by the macrophage system (alglucerase) occurred in CE 1992, and the remodeled recombinant protein, imiglucerase, as a biologic expressed in Chinese hamster ovary cells in CE 1994, in effect introduced the first 'blockbuster' orphan therapy. High costs of this therapy were justified by the excellent safety profile and salutary effects on key clinical manifestations of Gaucher disease.

The introduction and marketing of an effective biological treatment for Gaucher disease, based on biotechnological advances and a tri-partite arrangement between academia (The National Institutes of Health), investors, and an influential patient organization (National Gaucher Foundation) brokered by the emerging small biotech company Genzyme, was a spectacular affirmation of the value of the Orphan Drug Act. Within a few years, targeted molecular therapy for Gaucher disease placed the Genzyme Corporation in the forefront of technology and enabled it to diversify its activities in an orphan disease context and thereby develop treatments for other ultra-rare diseases.

The Genzyme Corporation was first-in-class for lysosomal diseases and was one of few biotechnology companies that were almost immediately successful in the orphan disease field. Space does not permit full discussion of the Genzyme Corporation and events induced by viral contamination of bioreactors for enzyme manufacture. Regulatory shutdown of the production facility in the core biological manufacturing businesses led to takeover by Sanofi Aventis – a French pharmaceutical giant. While it would be unusual for a major biopharmaceutical companies to continue its own experimental medicine program, hitherto there has been sustained development by Genzyme as a distinct business unit within Sanofi.

After reports of the effect of miglustat in Gaucher disease, Genzyme developed an in-house program in association with Drs. Radin and Shayman (University of Michigan) to develop a portfolio of biosynthetic inhibitors for clinical application in the sphingolipidoses. It is unusual for a biopharmaceutical company to develop self-competitive products; but in the mature era of enzyme therapy for Gaucher disease, with competing drugs from Shire and the Israeli company Protalix, adopted for this purpose by the Pfizer company, introduction

of orally active agents with an innovative mode of action presented an unusual opportunity.

Mucopolysaccharidoses

As discussed elsewhere, intensive biochemical studies of fibroblasts cultured from genetically distinct forms of the MPS by Elizabeth Neufeld, William Sly, and later Stuart Kornfeld and Kurt von Figura and their colleagues revealed much through studies of functional complementation about receptor-mediated uptake molecules harboring a common lysosomal recognition marker and serving as corrective factors that define specific clinical syndromes for enzymatic therapy. After many years of scientific research to determine the molecular events leading to an understanding of the sorting of proteins destined for delivery to the lysosomal compartment, it is gratifying to see that the MPS are well represented in the canon of lysosomal disorders for which specific therapy has been adopted by biopharmaceutical companies.

These disorders form a convenient group of conditions where there is impaired handling of complex glycosaminoglycans which are widely distributed molecular components in connective tissues including joints, heart valves, skeleton, and in vascular and extra-vascular spaces throughout the body. Each defect is reflected in the accumulation of mucopolysaccharide fragments, particularly dermatan, keratin, heparin, and chondroitin that are constituents of macromolecular proteoglycans. These complex molecules are principally responsible for maintaining tissue integrity.

Patients with mucopolysaccharidoses have bony abnormalities and joint stiffness. Those MPS diseases associated with accumulation of heparan sulfate may be particularly associated with brain disease: thickening of the leptomeninges, and the accumulation of excess cognate glycosaminoglycans in neural cells. Patients typically have coarse features and short stature, with abnormalities of dentition and distorted cartilage within the upper respiratory tract. The heart valves may be distorted by outgrowth of calcified fibrous tissue containing excess pathological glycosaminoglycans; neural cells show cytoplasmic vacuolation and abundant storage granules.

Recombinant human α -L-iduronidase is given intravenously for MPS1 (Hurler, Hurler-Scheie, and Scheie syndromes) after years of intensive laboratory study. Not only does the enzyme therapy diminish the excretion of excess glycosaminoglycans in the urine, but enlargement of the liver is decreased with improved rate of skeletal growth and range of joint movement. The treatment also improves the disease in the upper airways, with a helpful improvement in the episodes of hypoventilation occurring during sleep. In this condition, although many patients develop antibodies against the infused protein, usually only transient immune reactions occur and a degree of efficacy appears to be maintained.

Other mucopolysaccharidoses

Enzyme therapy has been introduced for several MPS syndromes, most notably MPS2 (Hunter disease). The activity of recombinant iduronate sulfatase in which, as with other sulfatases, enzymatic activity is dependent on the posttranslational modification of an active-site cysteine to formylglycine, decorated by mannose 6-phosphate residues to allow specific binding to the cognate receptors on the cell surface. The

commercial preparation, idursulfase, has principally been studied in individuals with the attenuated form of Hunter disease, showing improvement in mobility and respiratory difficulties. Since proteins do not materially traverse the blood-brain barrier, enzyme treatment does not improve the cognitive and related features of MPS2 affecting the brain, and since the 1980s, following poor results of hematopoietic stem-cell (marrow) transplantation, there has been a moratorium on this latter modality.

In MPS6 (Maroteaux-Lamy disease), recombinant *N*-acetyl-galactosamine 4-sulfatase (arylsulfatase B – BioMarin Pharmaceuticals) has been approved for clinical use and improves the systemic manifestations of this condition in which cognitive impairment is unusual. Intravenous infusions improve walking and stair climbing capacity in patients with MPS6.

MPS4a (Morquio disease)

BioMarin Pharmaceuticals have used recombinant mannose 6-phosphate-decorated human *N*-acetylgalactosamine-6-sulfatase to clear keratan sulfate from the lysosomal compartment and arrest progression of this disease, which has very striking effects with abnormal thoracic bone structure and vertebral development that impede ventilatory capacity and distorted limbs due to short stature and lax joints. Together with subluxation of the atlantoaxial joint, impair mobility and may be fatal. Randomized placebo-controlled Phase 3 trials have shown that infusion of 2 mg/kg⁻¹ of the recombinant protein on a weekly basis improves six-minute walk tests and other secondary outcome measures, together with the coherent improvements in urine excretion of keratan sulfate. As with all the sulfatase enzymes, active product requires activation of the critical cysteine through the agency of the SUMF as an additional hurdle in the biopharmaceutical manufacturing of advanced biologic therapies. A summary of approved enzyme therapies currently authorized as biologics is available (Baldo, 2015).

Therapeutic Stratagems for Lysosomal Diseases with Neurological Manifestations

Most lysosomal diseases are associated with neurological effects, some of which, as in the lysosomal diseases such as Tay-Sachs, with primary defects in the metabolism of sphingolipids, prove fatal in infancy. As the nervous system is formed, the neurones and supporting glia only rarely undergo mitosis and thus depend heavily on lysosomes to recycle many critical components. These include large tracts of membrane, synaptic vesicles, an extensive endoplasmic reticulum, and abundant mitochondria and peroxisomes, durably throughout the lifetime of the cell. By the same token, neurodegenerative diseases have severe effects on the individual and remain a challenge for medical science. While delivery of complementing factors in the form of lysosomal hydrolases has proved relatively straightforward in the treatment of systemic disease, therapeutic targeting of lysosomes that are essential for the normal functioning of the nervous system has proved difficult. With their signaling functions and rich expression in neural cells, disorders of lysosomal breakdown of sphingolipids has been a focus of intense

research offering considerable promise that, sooner or later, definitive treatments will become available.

Principal therapeutic stratagems:

- i. Use of substrate biosynthesis inhibitors (substrate-reduction – or rebalancing – therapy)
- ii. Direct enzymatic augmentation
- iii. Gene transfer.

Enzymatic Augmentation

Attempts to ameliorate neurological aspects of lysosomal diseases by enzyme therapy

Recombinant enzymes to restore the deficient activities in Sanfilippo diseases A and B have been explored with mixed results. MPS3 (A–D) have rather inconspicuous systemic effects, compared with the florid progressive cognitive impairment associated with agitation and behavioral abnormalities. Attempts are being made to determine whether intrathecal administration of sulfamidase will have any benefit in either preventing cognitive decline or possibly improving some aspects of the neurological phenotype of MPS1. However, despite the heroic nature of such trials, the difficulties of administering recombinant human proteins safely in highly mobile and behaviorally disturbed children with these conditions cannot be underestimated. A similar trial has been underway in MPS2, in which heparin sulfate also accumulates. Characteristically there is progressive cognitive impairment in most boys and men with the X-linked Hunter syndrome.

Enzyme therapies have also been in development for a very rare disorder: α -mannosidosis with a recombinant preparation following longstanding preclinical animal studies which showed benefit of this therapy. In this very rare glycoproteinosis with a birth frequency of approximately 1:1 000 000, undegraded polysaccharide intermediates resulting from the failure to digest mannose-containing glycoproteins lead to mild skeletal abnormalities and progressive impairment of mental function, including speech. While hematopoietic stem-cell (bone marrow) transplantation has been reported in some cases to arrest the progression of the disease, due to current infection and other complications, as well as the rarity of the disorder, render this evidence rather tentative and the results of recent enzyme replacement trials with recombinant α -mannosidase supported by a European project are awaited.

Niemann–Pick disease types A and B

Niemann–Pick Disease Types A and B are caused by deficiency of acid sphingomyelinase – a sphingolipid disorder associated with hepatosplenomegaly. In the severe Type A form, with markedly disabling mutations in ASM, there is accumulation of sphingomyelin in the brain with the buildup of secondary lipids, including ceramide and sphingosine. Although the molecular pathogenesis is not fully understood, in both forms – A, and the less severe peripheral B subtype, B – the presence of large foam cells, which are abnormal macrophages is associated with inflammatory cell infiltration in the parenchymal organs. There is marked enlargement of the liver and spleen with infiltration of the lung. Splenic sequestration of the formed elements of the blood with bleeding tendencies due to reduced circulating platelets with anemia and reduced

neutrophilic leukocytes, causing susceptibility to microbial infection also occur. For many years, enzyme therapy has been studied in preclinical models of Niemann–Pick diseases type A and B, and although the potential release of ceramide by recombinant acid sphingomyelinase targeted to cells via the mannose 6-phosphate and mannose receptors therapeutic dosing has been undertaken cautiously. Increasing doses of the putative therapeutic acid sphingomyelinase has been infused to determine whether the expected benefit can be achieved in the parenchymal organs without inducing catastrophic activation of apoptosis in the presence of excess ceramide. Since the administered enzyme does not penetrate the blood–brain barrier, it is unlikely that the progressive cognitive defects and neuro-developmental abnormalities that characterize the severe Niemann–Pick A variant will never be susceptible to correction by systemic enzyme therapy in whatever dose is ultimately chosen for therapeutic application.

Substrate-Reduction

There has been increasing interest in the development of inhibitors of sphingolipid biosynthesis that can be used to ameliorate the over-production of toxic sphingolipids in conditions when their recycling in the lysosome is impaired – thus restoring a normal equilibrium between biosynthesis and degradation of these bioactive macromolecules. The substrate-reducing stratagem, which has led to the introduction of two approved small molecules for the treatment of the systemic manifestations of Gaucher disease and miglustat for the neurological manifestations of Niemann–Pick disease type C, is discussed above.

Gene Transfer

The transfer of human cDNAs encoding the cognate wild-type sequence corresponding to the appropriate protein with impaired function as a result of mutation has been effective in preclinical animal models of lysosomal diseases and is undergoing testing formally in Phase I and Phase II in clinical trials. Lysosomal diseases have the potential for successful correction, since the secretion-recapture system forms the basis of enzyme augmentation therapy. Thus *in situ* complementation of the lysosomal deficit if successful will either ameliorate, arrest or even reverse the evolution of the disease (Cachón-González *et al.*, 2012). In most cases, where this stratagem has proved successful in living animals, viral vector systems have been utilized. In this case, the transduced cells act as a source of functioning enzyme that is released to effect the therapeutic complementation by uptake at a distance (Cachón-González *et al.*, 2012) so that theoretically, at least, the more enzyme generated and released, the greater will be the extent of correction through receptor-mediated uptake. As in humans, naturally occurring models of lysosomal diseases occur frequently in animals, and these serve as authentic experimental systems for therapeutic exploration, since they are almost invariably coherent biochemically and genetically. Emphasis here is placed on lysosomal diseases that affect the nervous system, principally because untreated neurodegenerative conditions have extreme human and medical costs – they

moreover represent challenges to establish widespread and effective therapeutic complementation that is sustained. Thus, the main challenges are generating sufficient delivery and distribution of the therapeutic product in all tissues at risk from injurious pathology, as exemplified by the brain, and to some extent the spinal cord. A further requirement is the capacity to sustain expression of the corrective gene, which can be safely transduced. Two principal methods have been adopted:

(i) Direct administration of vectors to the brain

Lysosomal diseases with neurodegenerative effects are in the vanguard of clinical studies of gene therapy. The success of interventions for inherited retinal diseases and hemophilia based on many years work with vectors that proved suitable for long-term expression and stratagems that avoid immune shutdown provides confidence that has hitherto been lacking. Moreover, 'risk-adverse' biotechnology companies are investing in academic developments with cautious support and sometimes collaborative investment in early clinical trials. Currently, the most promising vectors for this application are based on recombinant adeno-associated viral vectors, which are delivered by intra-cerebral injection using neurosurgical procedures to various brain structures. This is a passenger virus which does not integrate frequently into the genome. These episomal vectors have many advantages and appear to be safe when injected into white matter, for example in primates. These lysosomal enzymes have a 'housekeeping' property beyond the productive focus of expression and uptake via self-service receptors of the mannose 6-class may well overcome the barriers to supply corrective proteins distributed over an extensive target field. Recombinant AAV vectors containing limited expression and regulatory elements, as well as the cDNA encoding the lysosomal hydrolase of interest, are capable of inducing long-term sustained expression of the enzymes at activity levels predicted to have useful therapeutic effects (Cachón-González *et al.*, 2012).

A clinical Phase 1/2 study using the rAAV-2 serotype vector has been undertaken without ill effect in infantile neuronal lipofuscinosis Type 2 (NCL2) and was administered to several patients at several cranial entry sites expeditiously and without overt ill effect. These studies emboldened later trials using high-expression vectors in this and other fatal lysosomal diseases with neurodegeneration. Targets for this approach with recombinant AAV vectors, principally using the serotype rh.10, have been underway with Sanfilippo A disease (Tardieu *et al.*, 2014), Sanfilippo B disease, and, at the time of writing, initiated in metachromatic leukodystrophy. It is notable that all of these three trials are being undertaken in Paris, France, where there are several leading groups pioneering gene therapy for lysosomal diseases, principally using rAAV vector technology. Further studies are planned in GM1 gangliosidosis and also GM2 gangliosidosis (Tay-Sachs disease) and are at the immediate non-clinical developmental stage.

While gene therapy is still in its clinical infancy, it has nonetheless been delivered so far safely as a regulated and approved entity in several lysosomal diseases with neurological effects. However, design of future trials will be critical to determine whether or not efficacy can be demonstrated in patients stricken with such severe diseases. This poses the

question of whether the procedure can be justified in rapidly fatal diseases or those with indolent effects on the nervous system since heterogeneous manifestations in the latter pose difficulties for quantifying outcome.

Direct administration of vectors to the brain may prove to be too laborious as well as dangerous: recent research has shown that members of the AAV9 serotype vector family have potential penetrating properties toward the blood-brain barrier; this applies to adult animals in which the barrier robustly excludes soluble proteins and viruses. In some experimental systems it has been possible to transduce the nervous system via a single peripheral injection administered intravenously. The recent report of a high proportion of tumors in mice with GM2 gangliosidosis that received systemic rAAV9 in the neonatal period raises some concern about oncogenicity of this virus system. However, it seems likely that the long-term experience with successful human rAAV therapy in hemophilia B (Factor IX deficiency) will supply the necessary confidence to persist in this field of therapeutic research.

(ii) Indirect use of vector-transduced autologous hematopoietic stem-cells which are re-infused

This latter technique is built upon early indications of efficacy, based on hematopoietic stem-cell transplantation, first exploited with bone marrow donors but latterly donor stem-cells in peripheral blood elicited by the administration of both factors, such as GCSF. However, a typically suitable HLA-matched sibling or unrelated donor is not available, and the mortality of this procedure remains appreciable.

Ex-vivo hematopoietic stem-cell gene (reinfusion) therapy enhances the weak therapeutic effects observed after cellular complementation delivered to the peripheral circulation, where the peripheral manifestations of disease may be corrected, but there are only limited salutary effects on the brain depending on the degree to which donor mononuclear phagocyte precursors leave the circulation to populate the brain as resident macrophages and microglia.

Over three decades since the first clinical attempts at retroviral transfer of genes into hematopoietic progenitor cells, the concept of a therapeutic Trojan horse has been developed. This has been explored clinically by the group of Naldini and colleagues in the San Raffaele University in Milan in the severe white-matter disease Infantile Metachromatic Leukodystrophy (due to mutations in arylsulfatase A). Unusually for a lysosomal disorder, the genetically modified murine model of arylsulfatase deficiency appears unrepresentative of metachromatic leukodystrophy; unlike human patients, the mice show limited if any demyelination and do not suffer acute neurodegeneration. Microscopic abnormalities that are present in the brain of the animals bear little resemblance to the human disease in infancy; hypomyelination and demyelination are not prominent.

Biffi and colleagues recently reported a Phase 1/2 clinical trial in which transfer of wild-type human arylsulfatase A into autologous CD34⁺ hematopoietic progenitor cells was harvested from three unrelated infants who had been diagnosed early in the course of the disease at the pre-symptomatic phase, as a consequence of metachromatic leukodystrophy in their older siblings (Biffi *et al.*, 2013). Transduction of the CD34⁺ cells was stimulated *ex-vivo* with early-acting cytokines, brought about by exposure to purified third-generation lentiviral vectors

expressing human arylsulfatase A cDNA under the control of the phosphoglycerate kinase promoter. After expansion *ex-vivo*, the transduced progenitor cells were re-infused into their hosts, who had undergone substantial myeloablation without immune-suppression. Biffi *et al.* confirmed the stable engraftment of the transduced cells, no evidence of aberrant clonal behavior or preferential integration of the vectors. Arylsulfatase A was expressed in excess of the normal reference range in hematopoietic lineage. In an earlier report, evidence that this intervention had salutary effects is provided by the delayed onset and attenuated course of metachromatic leukodystrophy in recipients compared with their untreated siblings and studies of the natural course of the disease. While very encouraging, formal proof that, when given in the early pre-symptomatic phase of a lysosomal disease, this approach provides unequivocally superior outcomes than use of untransduced donor hematopoietic stem-cells, is not yet absolute and the therapeutic position of this ingenious stratagem is yet to be established.

Advances in the Field

Future Prospects in Clinical Research

Interdisciplinary exploration of the pathophysiology and biology of the lysosome has entered an accelerated phase: molecular therapies with salutary effects have allowed the aims of orphan drug legislation to be realized – and with several effective biologics approved, commercial returns have in notable cases catalyzed collaborative discovery in academic and biopharmaceutical environments. At a practical level, enhanced awareness of individual lysosomal disorders and the need for expertise in the management of multisystem disease, together with effective treatments leading to improved life-quality and survival to adulthood, attracts patients to academic centers. Thus investigators are increasingly drawn into a field enriched by genuine opportunities for translational bioscience with burgeoning clinical application: these include gene transfer and cell-based therapies which exploit the lysosomal network as a route for functional complementation.

Gaucher Disease – Insights Emerging from Exploring Ultra-Rare Lysosomal Disorders

Commercial and scientific opportunities and the humanitarian need for orally active agents with the potential to improve the convenience of treatment for Gaucher patients internationally, and ultimately address disabling neurological manifestations, are attractive for scientists and physicians alike. Furthermore, continued study of Gaucher disease has revealed important and, at present, poorly understood comorbidities; these include Parkinsonism, arterio-vascular and cardiac disease, as well as cancers – preferentially myeloma and B-cell lymphoma. Thus development of inhibitors of glycosphingolipid biosynthesis with therapeutic potential and which enter the nervous system promises to open up fundamental aspects of sphingolipid metabolism to another level of understanding. Moreover, the ability of small molecules rather than the first effective cell-targeted biologics to access tissues beyond the macrophage compartment is expected to shed light on

carcinogenesis, particularly in B cells. In this way, a single lysosomal disease continues to serve as a discovery platform and an example of unexpected insights gained from investigation in an ultra-rare disease.

Manipulating Macromolecular Biosynthesis and Substrate Loading in the Lysosome

One avenue for advancement is the fusion of combinatorial biosyntheses with identification of selective therapeutic inhibitors that allow rebalancing of metabolic fluxes in the lysosome. The utility of this stratagem has been validated in the glycosphingolipidoses, such as Gaucher disease, in which accumulation of poorly recycled macromolecules initiates cascades in the cell which lead to the partially compensated pathological complex of clinical disease. The ultimate reward of this approach will be judged by the ability favorably to attenuate lysosomal diseases that affect the brain. Several promising ‘small-molecule’ inhibitors that traverse the blood–brain barrier are being examined in the severely disabling human sphingolipid diseases, including Fabry disease and the gangliosidoses.

Hitherto, investigators have proved less successful in identifying suitable inhibitors of other rate-limiting steps in the biosynthesis or intracellular delivery of macromolecular substrates such as glycoproteins or glycosaminoglycans to the lysosome for degradation but intensified screening of compounds against refined biochemical reaction targets in this field is likely to be rewarding. To address the specific consequences of pathological storage, further exploration of molecular chaperones, including heat-shock protein-inducers to enhance exocytosis of lysosomal contents is clearly warranted; and while manipulation of the transcriptional control of the master-regulator TFEB (reciprocally to interrogate lysosomal biogenesis and autophagy) may be ambitious because of the theoretical possibility of cell toxicity or uncontrolled nutrient signaling and growth, this would also represent a fundamental molecular target for therapeutic exploration.

Pathogenesis and Physiological Understanding

Discovery of the lysosome (and peroxisome) was essentially coincident with the inception of Cell Biology as a credible domain of experimental science. It is remarkable how many advances in understanding the physiological rôle of the lysosome have been elucidated from investigating inborn errors causing human diseases which affect the biogenesis and function of the organelle. With more than 70 distinct individual human phenotypes in the lexicon of hereditary lysosomal diseases and disorders of lysosome-related organelles and biogenesis, together with whole-exome sequencing and bioinformatic analysis for improved molecular diagnosis, the stage is set for a knowledge explosion. Principally this will be based on the critical insights obtained from the detailed characterization of human diseases. Widespread incursion of genome-wide studies into the study of pathogenesis has identified variation in human phenotypes; those that affect the function of genes encoding proteins implicated in lysosome biology are numerous. Thus while the central rôle of the

lysosomal compartment in the inner workings of the cell is no longer in doubt, the importance of the organelle in general pathology has yet to be fully realized.

Conclusion

The pathological sciences and cell biology have coevolved and will continue to advance hand in hand through common technologies. Ready availability of interventional genetics and powerful microscopes that combine immunological and confocal fluorescence-based methods allow the cell to be explored dynamically. Through this we are able to identify the molecular interactions of neo-prismatic structures identified in living cells. Thus a discovery-horizon founded on an old scientific tradition has been generated: the study of informative mutant phenotypes paradigmatically represented by lysosomal diseases.

Glossary

Autolysosome An acidic degradative hybrid organelle formed by a fusion event between a lysosome and an autophagosome.

Autophagosomes Double membrane bound vesicles that encapsulate cytoplasmic components which eventually fuse with lysosomes.

Chronic obstructive pulmonary disease (COPD) A type of obstructive lung disease characterized by airflow limitation that is not fully reversible and encompasses conditions often described with the terms emphysema and chronic bronchitis. The airflow limitation is typically progressive and is associated with an abnormal inflammatory response of the lungs to noxious particle or gases primarily caused by cigarette smoking and breathing polluted air.

Cirrhosis A medical condition associated with severe liver damage and is characterized by conversion of normal liver tissue by fibrosis and structurally abnormal regenerative nodules. These changes can often lead to loss of liver function.

Cytostatic Inhibition of cell growth.

Dysplasia A term used in pathology to describe the enlargement of an organ or tissue caused by deregulated proliferation of cells of an abnormal type.

Emphysema A term used in pathology which refers to the destruction of the gas-exchanging surfaces of the lung.

Endoplasmic reticulum-associated protein degradation (ERAD) A cellular protein quality control pathway which targets misfolded proteins from the endoplasmic reticulum to be degraded by the proteasome. The proteins targeted for degradation often undergo ubiquitination.

Fibrosis The formation or deposition of excess fibrous connective tissue (scar tissue) in an organ.

Hepatectomy Surgical excision of the liver.

Hepatocellular carcinoma Malignant tumor arising from hepatocytes as the primary source.

Hepatocyte An epithelial parenchymatous cell of the liver that synthesizes and secretes bile. Hepatocytes constitute ~70–85% of the cytoplasmic mass of liver.

High throughput Rapid automated analysis of various substances using robotics technology.

Huntington's disease A specific type of neurodegenerative disorder that affects muscle coordination and leads to progressive decline of cognitive abilities and results in neuropsychiatric manifestations.

Induced pluripotent stem cells (iPS) Genetically reprogrammed adult cells that mimic several properties of an embryonic stem cell. The reprogramming is performed by expressing specific genes and factors critical for maintaining the defining properties of embryonic stem cells.

Metalloprotease A protease which requires a metal for its catalytic function.

Peptidomimetic A small protein-like chain designed to mimic a biologically active peptide with precisely altered molecular structure to introduce additional properties such as enhanced stability or biological activity.

Protease Any enzyme that cleaves a protein by hydrolyzing the peptide bonds that link amino acids together in the polypeptide chain forming the protein.

Proteostasis Proteostasis or protein homeostasis is a complex regulatory process that maintains proper repertoire of proteins within the cell which is critical for the health of the cellular proteome as well as the organism itself. This involves complex interplay of integrated network of subcellular pathways that influence the fate of a protein from synthesis to degradation. Dysfunction of any of the proteostatic pathways could lead to various cellular disorders and eventually diseases.

Proteotoxicity Impairment of cell function due to toxicity caused by accumulation of misfolded proteins.

Steatosis Abnormal retention of lipids in liver cells.

Introduction

The classical form of α 1-ATD is an autosomal co-dominant disease affecting 1 in 3000 live births. It is characterized by a point mutation that renders a major hepatic glycoprotein prone to misfolding in the early compartments of the secretory pathway. Liver disease, including fibrosis and carcinoma, is

caused by the accumulation/proteotoxicity of mutant α 1-antitrypsin Z (ATZ) in liver cells. Chronic obstructive pulmonary disease (COPD) is caused by excess protease activity that impacts the lung when levels of α 1-antitrypsin (AT) in the blood and body fluids are decreased (Figure 1).

Genetic and environmental modifiers have a major effect on the incidence and severity of lung and liver disease among

Figure 1 Pathophysiology of α 1-antitrypsin and its deficiency (ATD). Synthesis of AT in the liver and secretion into the circulation to protect the lung from neutrophil proteases in a normal individual is shown in the top panel. The classical form of ATD is depicted in the bottom panel with liver damage from accumulation of the mutant protein (gain-of-function) and lung damage due to protease excess (loss-of-function) shown in the bottom panel (image used with permission from The University of Utah Genetic Science Learning Center, <http://Learn.Genetics.utah.edu>).

ATD homozygotes. Multiple mechanisms have been implicated in the increased risk of COPD in affected ATD patients mediated by cigarette smoking, including active oxygen intermediates that abrogate proteinase inhibitory function of residual ATZ molecules. Variation in liver disease severity is thought to involve proteostasis mechanisms that mitigate the accumulation/proteotoxicity of the misfolded ATZ protein. Recent work has focused on the intracellular mechanisms by which the misfolded protein is degraded and specific adaptive

signaling pathways that are activated presumably to protect the cell (Ong and Kelly, 2011). This work has led to several novel therapeutic strategies which will be highlighted in this article.

Physiology and Function of AT

AT is a single-chain polypeptide with 394 amino acids and 3 asparagine-linked carbohydrate side-chains. It is encoded by a 12.2 Kb gene (SERPIN A1) located on human chromosome 14q31-32.2 (Long *et al.*, 1984). AT is synthesized as a 52-kDa partially glycosylated precursor and undergoes carbohydrate side-chain processing as it traverses the luminal secretory pathway from endoplasmic reticulum to Golgi and into the extracellular fluid with a half-time for secretion of 35–40 min (Lodish and Kong, 1987). The predominant site of synthesis of plasma AT is the liver, as shown by conversion of plasma AT to the donor protein isoform structure after orthotopic liver transplantation (Hood *et al.*, 1980). However, there is also evidence that AT is synthesized and secreted by extrahepatic cell types including monocytes and macrophages (Perlmutter *et al.*, 1985) and epithelial cells from a number of tissues (Koopman *et al.*, 1989; Carlson *et al.*, 1988; Perlmutter, 2011b).

Serum levels of AT increase by three- to five-fold during the host response to inflammation/tissue injury and so it is considered a typical 'acute phase reactant.' AT levels also increase during pregnancy and oral contraceptive therapy (reviewed in Teckman *et al.*, 1996). These changes in AT levels are believed to reflect regulation of gene expression at the transcriptional level by inflammatory cytokines, including IL-6, and by androgens (Perlmutter *et al.*, 1989). Expression of AT is also regulated by a feed-forward mechanism mediated through a receptor for AT-elastase complexes (Perlmutter *et al.*, 1990). Circulating AT diffuses into most tissues and body fluids at a concentration generally equivalent to that in plasma. It is cleared from the circulation with a half-time of ~ 5 days (Crystal, 1990). The daily production rate is estimated to be 34 mg kg^{-1} with 33% of the intravascular pool cleared and degraded daily.

The major physiological function of AT is inhibition of neutrophil elastase and several other serine proteases produced by neutrophils. It is the archetype of a family of structurally related proteins that are called SERPINS because most of the members are inhibitors of serine proteases. Although AT can inhibit multiple serine proteases *in vitro*, it is much more effective in inhibiting the neutrophil elastase, proteinase 3 and cathepsin G. Indeed the kinetics of its inhibitory activity for these neutrophil proteases are more favorable by several orders of magnitude and therefore these are believed to be its only physiological targets *in vivo* (Crystal, 1990). The protease inhibitory activity of AT may be modified by numerous factors but the effects of active oxygen intermediates and metalloproteases have been most well characterized. Active oxygen intermediate abrogate the elastase inhibitory properties of AT by oxidizing methionine at its reactive center (Hubbard *et al.*, 1987). Because cigarette smoking induces release of active oxygen intermediates by mononuclear phagocytes in the lung, this effect is believed to explain the increase in incidence and severity of destructive lung disease in ATD individuals that are

also smokers and is the essence of the 'protease-inhibitor imbalance,' or 'elastase-antielastase imbalance,' mechanism that causes the large majority of COPD cases in cigarette smokers who do not have ATD (Crystal, 1990). Metallo-proteases, either endogenous or expressed by invading microbes, are known to inactivate AT by proteolytic cleavage and therefore may also play a role in protease-inhibitor imbalance that contributes to the pathogenesis of COPD.

Mechanism of Deficiency in the Classical form of ATD

The mutant ATZ molecule is characterized by a single amino acid substitution, Lys for glu 342 (reviewed in Perlmutter,

2011a,b). This substitution is sufficient to decrease secretion with intracellular accumulation of the mutant protein. This alteration in biogenesis has been observed in multiple cell types and can explain the reduction in serum levels of AT that occurs in affected homozygotes (reviewed in Perlmutter, 2011a,b). The alteration in biogenesis and intracellular accumulation of mutant ATZ is selective in that the fate of other secretory proteins is not affected.

Studies by Lomas and colleagues and later by Huntington have shown that ATZ is prone to polymerization and aggregation (Lomas *et al.*, 1992; Belorgey *et al.*, 2007; Yamasaki *et al.*, 2008) and it now appears that the formation of insoluble polymers/aggregates play an important role in the pathobiology of liver disease (Figure 2). These investigators have also concluded that polymerization of ATZ is the cause of

Figure 2 Ribbon diagram to show the structure of mutant ATZ in a trimer as depicted by Yamasaki *et al.*, 2008. Three crystallographically related monomers assemble into the trimer through C-terminal domain swap shown in panel (a). Each monomer is shown in a different color. A model of an open trimer (b), colored as in panel (a), was created by breaking one intermolecular contact and orienting the protomers in a head-to-tail manner. The red monomer is able to donate the C terminus (donor) and the blue monomer can accept a C terminus (acceptor) to elongate or self-terminate. The lightning bolt indicates a site of likely proteolytic susceptibility. This trimer is thought to be one of probably multiple types of polymers/aggregates that ATZ forms. This diagram was reproduced with permission from Yamasaki, M., Li, W., Johnson, D.J., Huntington, J.A., 2008. Crystal structure of a stable dimer reveals the molecular basis of serpin polymerization. *Nature* 455, 1255–1258.

defective secretion and intracellular accumulation. The most convincing evidence for this conclusion is a series of studies in which secretion of ATZ is partially corrected by introduction of a second mutation that suppresses polymerization (Sidhar *et al.*, 1995). However, these results could not exclude the possibility that intracellular retention is caused by a distinct abnormality in folding that is also partially corrected by the second experimentally introduced mutation. Furthermore, there is numerous observations that militate against polymerization as the cause of defective secretion. First, naturally occurring variants of AT that do not polymerize are retained in the ER (Lin *et al.*, 2001). Second, only ~18% of the intracellular pool of ATZ at steady state is in the form of polymers in model cell lines characterized by marked ER retention (Lin *et al.*, 2001; Schmidt and Perlmutter, 2005). Third, peptides and peptidomimetic drugs which interfere with polymerization of ATZ do not correct the secretory defect but rather increase intracellular degradation (Alam *et al.*, 2012). Taken together, we believe the data are most consistent with the notion that altered folding leads to accumulation in the secretory pathway and that polymerization and aggregation of retained ATZ occurs secondarily – i.e., the primary effect is protein misfolding. This is not a trivial distinction because it means that chemical or genetic interventions that interfere with polymerization will not correct the primary secretory defect.

Cellular Mechanisms of Liver Disease

Over the years it has become clear that the liver disease which occurs in some individuals with ATD is caused by a gain-of-function mechanism triggered by aberrant accumulation of misfolded ATZ in the secretory pathway, a mechanism that has come to be referred to as ‘gain-of-function proteotoxicity’ in diseases caused by misfolded proteins (reviewed in Perlmutter and Silverman, 2011). The strongest evidence for this mechanism comes from transgenic mouse models of ATD that have hepatic histological findings that recapitulate what is seen in humans with ATD (Figure 3), including fibrosis with minimal inflammation, mild steatosis, glycogen depletion and carcinogenesis (Hidvegi *et al.*, 2010; Rudnick *et al.*, 2004; Marcus *et al.*, 2010). These effects cannot be from loss-of-function because the mice still express endogenous anti-elastases. Recent studies have also demonstrated intracellular accumulation of ATZ with proteotoxic consequences in a transgenic *Caenorhabditis elegans* model of ATD (Long *et al.*, 2014).

The mechanisms by which ATZ accumulation leads to cellular injury are not known but studies in mammalian cell line models and the PiZ mouse model of ATD have provided evidence for mitochondrial damage with caspase-3 activation *in vivo* (Teckman *et al.*, 2004; Teckman *et al.*, 2002). Similar alterations were noted in the liver of α 1-AT-deficient patients. Perhaps even more important, treatment of the PiZ mouse

Figure 3 Hepatic histopathology in α 1-antitrypsin deficiency. (a) Micrograph of liver section stained with periodic acid–Schiff (PAS) followed by diastase treatment. The section shows characteristic PAS-positive, diastase-resistant globules (arrows) and a band of fibrosis (arrowheads). (b) Electron micrograph of a biopsy specimen showing globules in endoplasmic reticulum. Globules (g) and ribosomes (arrowheads) are indicated. Panel (a) has been reproduced Wang, Y., Perlmutter, D.H., 2014. Targeting intracellular degradation pathways for treatment of liver disease caused by α 1-antitrypsin deficiency. *Pediatric Research* 75(1–2), 133–139 with permission from Nature Publishing Group. model with cyclosporine A, but not tacrolimus, resulted in a significant decrease in mitochondrial dysfunction, caspase-3 activation and mortality. Because CsA is known to inhibit the mitochondrial permeability transition but tacrolimus does not have this effect, the results implicate mitochondrial damage in the hepatocellular toxicity of ATD.

Fibrosis and eventually cirrhosis are the major pathological features of the liver in ATD. Studies using a transgenic mouse model with liver-specific inducible expression of misfolded ATZ, ideal for identifying changes in gene expression in response to ATZ accumulation, have shown that there is increased TGF β signaling which is likely to at least in part play a role in the hepatic fibrotic characteristics of ATD (Hidvegi *et al.*, 2007).

Although ATZ is known to polymerize and form insoluble aggregates, it is still not clear whether it is the polymers/aggregates that are cytotoxic or if monomeric forms of the misfolded protein are responsible. In at least one other disease caused by a misfolded protein, Alzheimer's disease (AD), soluble oligomers of amyloid β rather than insoluble aggregates are believed to mediate proteotoxicity (Haass and Selkoe, 2007). Indeed, some evidence in mouse models of AD suggests that aggregation of amyloid β prevents its cytotoxicity (Cohen *et al.*, 2009). Further studies designed to identify whether monomers, soluble oligomers or polymers/aggregates of ATZ are responsible for its cellular toxicity will represent an important advance for understanding the pathobiology.

Autopsy studies have shown that ATD is strongly associated with primary liver cancer (Eriksson *et al.*, 1986). Hepatocellular carcinoma also increases in the PiZ mouse model of ATD (Marcus *et al.*, 2010). Utilizing BrdU labeling Rudnick *et al.* have shown hyperproliferation in the liver of the PiZ mouse model. Although the increase in hepatocellular proliferation was five- to tenfold above the control mice and highly statistically significant, there was still a relatively low number of BrdU positive hepatocytes at one time (2–3% detected over 72h of continuous labeling). These data indicate that liver injury in the mouse model is relatively mild and appropriately corresponds to the slowly progressing liver disease that is seen in most ATD patients. Almost all of the proliferating hepatocytes were globule-devoid. The origin of these globule-devoid hepatocytes is not known, but they are known to have less total α 1-ATZ per cell and less polymerized α 1-ATZ per cell compared with the globule-containing hepatocytes (An *et al.*, 2005). These studies of (Rudnick *et al.*, 2004) show that globule-devoid hepatocytes have a selective proliferative advantage over the neighboring globule-containing cells and because of that there are zones of globule-devoid hepatocytes in every liver biopsy from patients with ATD and in liver from the mouse models of ATD. The zones of globule-devoid hepatocytes also increase with age, occupying more of the liver area over time (Perlmutter, 2011a,b; Geller *et al.*, 1990; Geller *et al.*, 1994). Hepatic cancers arise predominantly from the zones of globule-devoid hepatocytes (Zhou and Fischer, 1998; Zhou *et al.*, 2000; Hadzic *et al.*, 2006). Furthermore, the degree of proliferation of the globule-devoid hepatocytes is directly proportional to the number of globule-containing hepatocytes (Rudnick *et al.*, 2004). We have speculated that the globule-devoid hepatocytes are younger cells, eventually destined to become globule-containing hepatocytes, but there is a conti-

nuous supply of younger cells as a part of the ongoing regenerative activity (Rudnick and Perlmutter, 2005). The globule-containing hepatocytes have more aggregated ATZ, activation of autophagy, and NF κ B activation. They are relatively impaired in regeneration and, although they are undergoing cell death (Lindblad *et al.*, 2007), it is at a relatively low rate and so we believe that they are also relatively impaired in death. The term 'relative' is used to describe the impairment in proliferation and death because these globule-containing cells will proliferate and die at higher rates after partial hepatectomy, a much more powerful regenerative stimulus than the proteotoxic state that is generated by chronic intracellular accumulation of a 1-ATZ.

Based on these observations, it has been theorized that the globule-containing hepatocytes are 'sick but not dead' and are responsible for regenerative signaling, and the globule-devoid hepatocytes are the predominant ones that can respond to these signals (Rudnick and Perlmutter, 2005). This hypothesis is supported by recent studies in which normal hepatocytes repopulate the livers of PiZ mice (Ding *et al.*, 2011). Wild-type donor hepatocytes spontaneously repopulated the livers of PiZ mice, replacing 20–98% of mutant host hepatocytes. The normal cells were shown to initially divide almost exclusively around globule-containing hepatocytes. Later they replaced globule-devoid hepatocytes presumably because these cells are 'sick' compared with the normal donor cells even though they are relatively 'less sick' than the original globule-containing hepatocytes. In essence, the theory (Rudnick and Perlmutter, 2005) envisions that cross-talk between the globule-containing and globule-devoid cells perpetuate chronic hepatocellular proliferation, eventually leading to carcinogenesis within globule-devoid zones. The relative impairment in cell death in the globule-containing hepatocytes could account for the small number of cancers that do arise in these cells (Zhou and Fischer, 1998; Zhou *et al.*, 2000; Hadzic *et al.*, 2006).

Variation in the incidence and severity of liver disease among individuals with classical form of ATD was first described by Sveger using a cohort of 127 homozygotes identified by a nationwide screening study in Sweden (Sveger, 1976; Piitulainen *et al.*, 2005). This represents the only unbiased analysis and the results over 40 years since then indicate that only 8–10% of the cohort have experienced clinically significant liver disease. We now know that some ATD homozygotes develop severe liver disease during infancy, childhood, adolescence or even at 50–65 years of age and others appear to completely escape liver disease. These observations have led us to hypothesize that genetic or environmental modifiers determine liver disease susceptibility among ATD homozygotes. Furthermore we theorized that such modifiers would target proteostasis mechanisms such as intracellular degradation pathways or signaling pathways that facilitate cellular adaptations to aberrant intracellular ATZ accumulation. The hypothesis was first supported in 1994 when Wu *et al.* showed a lag in degradation of misfolded ATZ in genetically engineered fibroblast cell lines from ATD patients with severe liver disease as compared to cell lines from ATD patients without liver disease (Wu *et al.*, 1994). Recently these results have been confirmed using iPS-derived hepatocytes (iHeps) (Tafaleng *et al.*, 2013). Intracellular degradation was significantly more efficient in iHeps from ATD patients without liver disease with

a half-time of ~2 h compared to a half-time of ~4 h in iHeps from ATD patients with severe liver disease requiring transplantation during childhood. These results indicate that iHeps can be used to identify proteostatic modifier mechanisms in other forms of ATD liver disease, infantile, adolescent and the adult age-dependent form of the disease.

There is still relatively limited information about specific genes that represent the putative modifiers. Pan *et al.* described a polymorphism in ER mannosidase I, an enzyme involved in the ERAD pathway, in infants with severe liver disease due to ATD (Pan *et al.*, 2009). The polymorphism is thought to lower the levels of ER mannosidase I and, in so doing, to diminish degradation of misfolded proteins by the ERAD pathway (Pan *et al.*, 2009; Iannotti *et al.*, 2014). This putative modifier mechanism is consistent with the concept that the modifiers will target proteostasis mechanisms such as ERAD in this case. However, it is difficult to imagine that a partial decrease in ERAD would have enough effect to predispose to severe liver disease in the first year of life because there are several lines of evidence that other degradation pathways can compensate for decreases in ERAD activity. For one thing studies in yeast suggest that autophagy can be activated to compensate for higher levels of ATZ accumulation when the ERAD pathway is impaired (Kruse *et al.*, 2006a,b). Second, studies in the *C. elegans* model of ATD indicate that previously uncharacterized degradation pathways, which are otherwise held in reserve, may be activated when autophagy is impaired (Long *et al.*, 2014; O'Reilly *et al.*, 2014).

Cellular Mechanisms of Lung Disease

AT is an inhibitor of serine proteases in general, but its most important targets are neutrophil elastase, cathepsin G, and proteinase 3, proteases released by activated neutrophils. Several lines of evidence suggest that inhibition of these neutrophil proteases is the major physiologic function of AT (Crystal, 1990). First, individuals with α 1-AT deficiency are susceptible to premature development of emphysema, a lesion that can be induced in experimental animals by instillation of excessive amounts of neutrophil elastase. Second, the kinetics of association for AT and neutrophil elastase are more favorable by several orders of magnitude than any other serine protease. Third, AT constitutes more than 90% of the neutrophil elastase inhibitory activity. These observations point to the notion that destructive lung disease may result from hampering the net balance of elastase and AT within the local environment of the lung, the so-called elastase-antielastase imbalance. Cigarette smoking markedly accelerates the destructive lung disease that is associated with ATD. It reduces the quality of life, and significantly shortens longevity of these individuals (Crystal, 1990). The effect of cigarette smoking is thought to be due to oxidative and proteolytic inactivation of residual AT function by active oxygen intermediates and metallo-proteases released from mononuclear phagocytes (Crystal, 1990; Stockley *et al.*, 2009). Furthermore, in the vast majority of cases of chronic obstructive lung disease in which there is a history of cigarette smoking and no ATD, the elastase-antielastase imbalance theory revolves around the concept that levels of functional AT are reduced exclusively by

oxidative and proteolytic inactivation as a result of cigarette smoking.

Nevertheless, variability in the development of lung disease among individuals with ATD appears to occur even when cigarette smoking is taken into consideration (DeMeo *et al.*, 2009). Genome-wide association studies and integrative genomic approaches in COPD have demonstrated significant associations in ATD patients for single-nucleotide polymorphism (SNPs) in the chromosome 15q region that includes *CHRNA3* (cholinergic nicotine receptor α 3) and *IREB2* (iron regulatory binding protein 2) (Kim *et al.*, 2012). Other potential modifiers of lung disease in ATD include *NOS3*, *GSTP1*, *TNF*, and *IL10* (Kim *et al.*, 2012).

Several observations have raised the possibility that gain-of-toxic function mechanisms can also contribute to the pathogenesis of COPD in ATD. For instance, deposits of ATZ, which are known to be chemotactic for neutrophils, have been found in the extracellular matrix of the lung next to neutrophils (Mahadeva *et al.*, 2005). These observations are consistent with early observations that COPD associated with AT deficiency had a much higher degree of neutrophilic infiltration and accelerated inflammatory destruction than other causes of COPD (Crystal, 1990; Stockley *et al.*, 2009). There is also evidence for synthesis of AT in lung epithelial cells (Hu and Perlmutter, 2002). If accumulation of ATZ in respiratory epithelial cells has the same 'cytostatic' consequences as it has in liver cells (see below) that could theoretically cause respiratory epithelial dysfunction that contributes to the progression of COPD. The fact that replacement therapy with purified AT has not completely arrested the progression of COPD in AT deficiency makes the notion that gain-of-toxic function mechanisms contribute to the tissue injury more appealing.

Cellular Responses to Misfolding of Mutant ATZ

Research in many laboratories has focused on how cells respond to aberrant accumulation of misfolded proteins. Our work has been designed to characterize how cells respond specifically to accumulation of mutant ATZ in the early compartments of the secretory pathway with the hypothesis that such responses will explain how some ATD individuals escape liver disease. Two general types of 'proteostatic' mechanisms were envisioned, intracellular degradation pathways and signaling pathways that permit the cell to adapt to the proteotoxic state.

The proteasomal pathway was the first to be implicated in intracellular degradation of mutant ATZ. Studies in cell-free microsomal, mammalian cell line and yeast model systems indicated involvement of proteasomal machinery in degradation of mutant ATZ (Qu *et al.*, 1996; Werner *et al.*, 1996; Teckman *et al.*, 2001). The participation of both classical ubiquitin-dependent and -independent pathways was implicated in removal of ATZ via proteasomes as a part of what later was termed the ER-associated degradation (ERAD) pathway (Qu *et al.*, 1996). It has been our assumption that ERAD and the proteasomal pathway predominantly mediate degradation of soluble forms of ATZ that accumulate in the ER but this point has never been definitively

proven. Although many of the molecules that mediate ERAD have been elucidated since then, the specific molecules involved in proteasomal degradation of ATZ and the sequence of molecular events involved are still not completely characterized.

In early studies it was also clear that the proteasomal pathway could not completely account for intracellular degradation of ATZ in model systems (Qu *et al.*, 1996; Werner *et al.*, 1996; Teckman *et al.*, 2001; Teckman *et al.*, 2000; Cabral *et al.*, 2000; Cabral *et al.*, 2002). A critical role for autophagy in intracellular disposal of ATZ was initially established by observations in genetically engineered human fibroblast cell line models of ATD (Teckman and Perlmutter, 2000). Autophagy is a catabolic process by which cytoplasmic components are sequestered within double-membrane vesicles called autophagosomes, which then fuse with lysosomes to form autolysosomes where its contents are degraded by acidic lysosomal hydrolases. Autophagy is involved in removing damaged organelles and misfolded or dysfunctional proteins and is critical for maintaining cell health (Rubinshtein *et al.*, 2011). In addition to the dramatic increase in number of autophagosomes seen in fibroblast cell lines a marked increase in autophagosomes was observed in the liver of PiZ mice and liver biopsy specimens from ATD patients (Teckman and Perlmutter, 2000; Teckman *et al.*, 2002). A significant delay in ATZ degradation in genetically engineered autophagy-deficient mammalian cell lines and yeast model systems provided definitive evidence in the role of autophagy in ATZ disposal (Kamimoto *et al.*, 2006; Kruse *et al.*, 2006a,b). Studies in yeast that are deficient for ATG6 and ATG16 showed that degradation of ATZ was affected only when its expression was very high, suggesting that of ERAD/proteasomal pathways was sufficient for disposing of ATZ at lower levels of expression whereas autophagy was needed when ATZ accumulated to a higher extent, presumably reflecting the importance of autophagy in degradation of polymerized and insoluble ATZ aggregates (Kruse *et al.*, 2006a,b). Alternatively, higher expression of ATZ may lead to additional uncharacterized post-translational modification(s) on ATZ that could render them inaccessible to the ERAD/proteasome system. Studies in *C. elegans* model system for ATD have recently provided evidence for the involvement of both proteasomal and autophagic pathways in ATZ disposal (Long *et al.*, 2014). Also, treatment of cell lines with chemical inhibitors of autophagy results in partial attenuation of ATZ degradation (Teckman and Perlmutter, 2000), while, activators of autophagy results in augmentation of ATZ degradation (Hidvegi *et al.*, 2010). Together, these studies strongly suggest autophagy as a critical pathway in mutant ATZ disposal (Figure 4).

Several studies have suggested that mechanisms other than the proteasomal and autophagic pathways contribute to the intracellular disposal of mutant ATZ. One such pathway described in a yeast model system involves targeting of ATZ from Golgi or TGN to lysosomes for degradation (Kruse *et al.*, 2006a). A recent study indicates involvement of sortilin in degradation of ATZ by the Golgi-lysosomal pathway in yeast and mammalian cell line model systems (Gelling *et al.*, 2012). It is speculated that any dysfunctional or aberrantly folded ATZ molecules that escape from ER into the Golgi are degraded by this pathway.

Figure 4 Subcellular itinerary of wild-type and mutant $\alpha 1$ -antitrypsin Z. Wild-type $\alpha 1$ -antitrypsin (AT; represented by red dots) is transported through the conventional secretory pathway as shown at the top of the figure. Mutant $\alpha 1$ -Antitrypsin Z (ATZ) accumulates in the ER in soluble (green dots) and insoluble polymers/aggregates (blue aggregates). The proteasomal pathway degrades soluble ATZ. The autophagic pathway is specialized for degradation of insoluble polymers/aggregates but may also play a role in degradation of soluble forms of ATZ.

There are likely to be still other mechanisms by which cells can degrade mutant ATZ and it is also likely that the different mechanisms of ATZ degradation can be induced to compensate for each other when stressed. These compensatory phenomenon will need to be taken into consideration as we further define the modifiers of proteotoxicity.

We have also envisioned that cells may respond to accumulation of misfolded ATZ by activating signaling pathways that are designed to facilitate adaptation and survival of cells under proteotoxic conditions. Studies in cell lines and mouse transgenic model systems with inducible expression of ATZ have been particularly useful in delineating signaling pathways activated as a primary response to ATZ accumulation, because the induction of these pathways would potentially be obscured in constitutively expressing model systems (Kamimoto *et al.*, 2006; Hidvegi *et al.*, 2005; Hidvegi *et al.*, 2007). In addition to autophagic response, activation of NF κ B and TGF β signaling pathways has been observed both in *in vitro* and *in vivo* model systems that were designed to express ATZ inducibly (Hidvegi *et al.*, 2005; Hidvegi *et al.*, 2007). The role of TGF β signaling pathway in hepatic fibrosis is well known (Wynn, 2007), and is presumed to be one of the mechanisms by which hepatic fibrosis occurs in ATD. Intriguingly, accumulation of ATZ in the ER does not appear to activate the unfolded protein response (UPR) pathway in most experimental systems (Hidvegi *et al.*, 2005). The lack of detectable UPR in ATD could be due to the inherent property of ATZ to polymerize and form insoluble aggregates as accumulation of other non-polymerogenic AT mutants in ER results in activation of UPR (Hidvegi *et al.*, 2007). Lack of UPR could be one of the reasons why globule-containing 'sick' cells survive and

could eventually contribute to pathogenesis of hepatocellular carcinoma.

Activation of NF κ B is believed to be a particularly important adaptive response to proteotoxicity in ATD patients (Hidvegi *et al.*, 2005). Interestingly, the assembled NF κ B complex in response to ATZ accumulation has a protein profile that is distinct from the complex which assembles upon treatment of cells with tunicamycin or tumor necrosis factor (Mukherjee and Perlmutter, unpublished data). One of the consequences of NF κ B activation is downregulation of Egr1, which is a transcription factor essential for hepatocyte proliferation and regenerative responses following partial hepatectomy (Liao *et al.*, 2004). Studies indicate that NF κ B activation could be involved in regulating liver cell proliferation and pathogenesis of hepatocellular carcinoma in AT deficiency (Maeda *et al.*, 2005). Intriguingly, mating PiZ mouse with conditional hepatocyte-specific NF κ B-deficient mouse gives rise to offsprings that exhibit more severe inflammation, fibrosis, dysplasia, and steatosis, and an increase in the number of globule-containing hepatocytes (Mukherjee and Perlmutter, unpublished data). This indicates a likely role of NF κ B signaling pathway acting as a protective mechanism against liver damage in AT deficiency. Ongoing studies are aimed at deeper understanding of the role of NF κ B signaling in ATD.

Genomic analyses of PiZ mouse liver tissue have identified other gene expression changes in response to hepatic accumulation of ATZ *in vivo*. Notably, upregulation of regulator of G protein signaling 16 (RGS16), could lead to activation of autophagy in the liver in ATD (Hidvegi *et al.*, 2007). The effect of RGS16 is thought to be mediated via its antagonistic effect on Gai3 which is known to inhibit hepatic autophagy (Gohla *et al.*, 2007). However, the exact molecular mechanism(s) by which RGS16 affects autophagy in the presence of ATZ is yet to be delineated.

Therapies for ATD Liver Disease

Orthotopic liver transplantation is the only treatment currently available for severe liver disease due to ATD and 5-year survival rates are greater than 90% for children and greater than 80% for adults (Kemmer *et al.*, 2008). Several novel strategies for treatment of ATD liver disease that would obviate the need for organ transplantation and extended immunosuppression are currently being investigated.

One of the newer strategies involves drugs that enhance autophagy. The rationale for this approach is based on studies in cell line and animal models showing that autophagy is specifically activated when ATZ accumulates in cells and that autophagy participates in intracellular disposal of ATZ (Kamimoto *et al.*, 2006; Kruse *et al.*, 2006a,b). It is also based on the observation that ATD liver disease is being recognized more frequently at 50–65 years of age, an age period which is known to be associated with a decline in autophagy function. The approach was first tested validated in studies which showed that carbamazepine (CBZ) enhanced autophagic degradation of ATZ in mammalian cell line models of ATD and that this drug could reduce hepatic ATZ load and hepatic fibrosis *in vivo* using the PiZ mouse model of ATD (Hidvegi

et al., 2010). Because CBZ is FDA approved and has been extensively used in humans as an anticonvulsant and mood stabilizer it is now being tested in a Phase II/III clinical trial for severe liver disease due to ATD.

High throughput automated screening of a drug library (LOPAC) using a recently developed *C. elegans* model system for ATD has identified five hit compounds that reduce cellular ATZ load in a dose dependent manner (Gosai *et al.*, 2010). Four of these five compounds have autophagy enhancer activity and are FDA approved for use in clinical practice. Importantly, two of the hit compounds belong to phenothiazine drug family that is structurally related to tricyclic antidepressants, including CBZ. The phenothiazines have been shown to be effective in enhancing autophagic disposal of aggregation-prone protein huntingtin, which causes Huntington's disease (Tsvetkov *et al.*, 2010; Sarkar *et al.*, 2007; Zhang *et al.*, 2007). One of these drugs, fluphenazine, has been tested in the *C. elegans* model of ATD as well as in mammalian cell line models and in the PiZ mouse. The results show that fluphenazine a positive effect in all of the models with reduction in hepatic ATZ load and hepatic fibrosis *in vivo* (Li *et al.*, 2014). This type of high throughput screening strategy and two novel strategies for chemical and computational-based drug discovery using the autophagy enhancer drug paradigm and the phenothiazine structure will become extremely helpful for discovering additional drugs that could be used for treating liver disease due to ATD (Long *et al.*, 2014; O'Reilly *et al.*, 2014).

Several research groups are developing other strategies for enhancing autophagy that could potentially be used for treatment of ATD liver disease. A novel autophagy-inducing peptide Tat-beclin 1 has been characterized which augments degradation of mutant huntingtin and several invasive bacterial and viral pathogens (Kyei *et al.*, 2009; Shoji-Kawata *et al.*, 2013). This peptide has been suggested to be useful in treating a broad range of human diseases caused by proteotoxicity mediated by aggregation-prone proteins and infectious pathogens. Viral-mediated gene transfer of transcription factor EB (TFEB), a master gene that regulates autophagy and lysosomal gene expression, has been reported to reduce hepatic ATZ load and liver fibrosis in animal models (Pastore *et al.*, 2013). *In vitro* studies show that TFEB reduces ATZ load in autophagy-dependent manner. Thus TFEB appears to be an excellent target for potential therapeutic drugs. A number of other drugs which have been shown to enhance autophagy are described in other reviews (Ghouse *et al.*, 2014; Wang and Perlmutter, 2014; Rubinshtein *et al.*, 2012).

Several gene therapy approaches currently under investigation are based on knocking down expression of mutant ATZ gene using vectors that will also harbor gene for wild-type AT and thereby could address both gain-of-function proteotoxicity and loss-of-function mechanisms of disease in ATD (Li *et al.*, 2011; Mueller *et al.*, 2012). In one approach, adeno-associated virus harboring short-hairpin RNA to knockdown endogenous ATZ expression was used together with a codon-optimized wild-type AT transgene cassette (Li *et al.*, 2011). In the other approach, an adeno-associated virus harboring microRNA to silence endogenous AT gene expression was used together with a microRNA-resistant wild-type AT gene (Mueller *et al.*, 2012). Both the approaches led to significant

reduction in hepatic ATZ load and high levels of human AT in the serum of a transgenic mouse model of ATD. However, the effect on liver fibrosis was not as extensive and so further studies are needed to test whether more potent and widespread silencing would be more effective. A more recent study using antisense oligonucleotides to silence ATZ expression had a more extensive effect in reducing hepatic fibrosis in the PiZ mouse by subcutaneous injection twice per week for 4–8 weeks (Guo *et al.*, 2014).

A ‘structure-based’ screening strategy has been employed by several groups that aim at designing and identifying peptides to prevent polymerization of the mutant ATZ and assist in its secretion. A small molecule compound engineered to target a lateral hydrophobic cavity in ATZ prevented its polymerization, however, when tested in a cell line model, it was found to promote increased intracellular degradation and had minimal effect on secretion (Mallya *et al.*, 2007). Another small molecule peptide targeting the reactive center loop of AT has been tested in cell line model systems, and was reported to promote increased secretion ATZ and reversed levels of polymerized ATZ. However, the efficiency of this peptide in reducing ATZ load and liver damage in animal models is yet to be tested (Alam *et al.*, 2012). Although promising, the use of this strategy in treatment of ATD will require rigorous studies to identify drugs based on the peptide sequence and thorough testing for their safety and efficacy.

The use of chemical chaperones that can facilitate folding of multiple misfolded proteins non-selectively have also been investigated as a potential therapeutic class for treatment of ATD. Among the chemical chaperones tested, glycerol and 4-phenylbutyric acid (PBA) were found to mediate a dramatic increase in the secretion of ATZ in mammalian cell culture model system (Burrows *et al.*, 2000). PBA, in particular, enhanced secretion of functionally active ATZ in cell culture model system. Importantly, oral administration of PBA in PiZ mice mediated an increase in blood levels of human AT reaching 20–50% of the levels present in PiM mice and normal humans. Because PBA has been used safely in clinical studies in humans, it was considered an excellent candidate for chemoprophylaxis of target organ injury in ATD. However, preliminary studies in ten patients with ATD-associated liver disease, provided no significant evidence of enhancement of serum levels of AT after 14 days of treatment with PBA. Lack of apparent effects of PBA could be due to insufficient duration of treatment time or inability of patients with chronic liver disease to tolerate large dose of this drug required for its function in humans (Teckman, 2004). As PBA selectively affects ATZ secretion and mediates its effect *in vivo*, it is required to further investigate its therapeutic potential if more favorable formulations become available. Recently, a drug similar to PBA, suberoylanilide hydroxamic acid (SAHA), has been reported to increase secretion of ATZ in cell line models of ATD (Bouchecareilh *et al.*, 2012). However, further studies are required to delineate whether this effect is due to increased synthesis of ATZ or due to its ability to reduce ATZ accumulation in cells. If the increased secretion of ATZ is primarily due to its increased synthesis, this may pose problems as treatment with SAHA may lead to increased cellular proteotoxicity in ATD patients. Moreover, rigorous studies remain to be

performed to study the effect of SAHA using *in vivo* models of ATD.

Hepatocyte transplantation therapy as an alternative to whole liver transplantation has been used successfully in treatment of several metabolic liver diseases (Fox *et al.*, 1998; Muraca *et al.*, 2002) and is now performed in at least 12 centers in 10 countries. Recent studies show that wild-type donor hepatocytes can repopulate almost the entire liver of the PiZ mouse model of ATD (Ding *et al.*, 2011). As the transplanted hepatocytes have a selective proliferative advantage over ATZ-containing endogenous hepatocytes and can replace the latter in a diseased liver, this type of therapy holds a potential to prevent ATD-associated COPD and possibly liver diseases.

In addition to these strategies, a combinatorial method of cell-based therapy and gene targeting could be a novel approach for treating COPD and liver diseases in ATD. Recent studies have shown that the mutation in the AT gene was corrected in human induced pluripotent stem (iPS) cells derived from an ATD patient homozygous for ATZ using a combination of zinc-finger nucleases and transposon techniques. Moreover, the corrected iPS cell lines could be successfully engrafted into the liver of a transgenic mouse model (Yusa *et al.*, 2011). This strategy, if adapted successfully for use in clinical application, has the potential to correct both the loss-of-function and gain-of-function mechanisms, and would have the advantage of personalized treatment options which will obviate the need for immunosuppression.

Therapies for ATD Lung Disease

Avoidance of cigarette smoking is a critical part of preventing lung disease and its progression. Replacement therapy with purified AT and lung transplantation are the two approaches currently used for treatment of severe COPD due to ATD. Replacement therapy has been shown to correct the decrease in AT levels and in neutrophil elastase inhibitory activity in bronchoalveolar lavage fluid (Crystal, 1990). Even though this therapeutic strategy has been used for over 20 years, there is still no evidence that it arrests the progression of ATD lung disease. Some studies have shown slowing of decline in forced expiratory volume in a subgroup of patients (Abboud *et al.*, 2005). The lack of clinical efficacy is likely due to multiple factors, including the fact that replacement therapy is only initiated late in the evolution of the disease and also that gain-of-function mechanisms contribute to the disease. Lung transplantation therapy has been used in over 2000 patients with ATD since 1995 with 50% of the recipients surviving after 8.6 years (Christie *et al.*, 2012).

EDITORS-IN-CHIEF

Ralph A Bradshaw is Professor Emeritus in the Department of Physiology and Biophysics at the University of California, Irvine. Prior to that he was on the faculty of the Department of Biological Chemistry, Washington University School of Medicine in St. Louis, MO and was Professor and Chair of the Department of Biological Chemistry at University of California, Irvine. From 2006 to 2015, he was a member of the Mass Spectrometry Facility and Professor of Pharmaceutical Chemistry at the University of California, San Francisco. He holds degrees from Colby College and Duke University and was a post-doctoral fellow at Indiana University and the University of Washington. He has served as president of FASEB, was the founding president of the Protein Society and was the treasurer of the American Society for Biochemistry and Molecular Biology. His research has focused on protein chemistry and proteomics, with emphasis on the structure and function of growth factors and their receptors, particularly nerve growth factor and fibroblast growth factor, and the involvement of receptor tyrosine kinases in cell signaling. He has also studied the role of proteolytic processing and N-terminal modification in protein stability and turnover.

Philip D Stahl is E. Mallinckrodt Jr. Professor Emeritus at Washington University School of Medicine in St. Louis, MO. He was educated at West Virginia University with post-doctoral work at Vanderbilt University. He served as Head of the Department of Cell Biology and Physiology and Director of the Division of Biology and Biomedical Sciences at Washington University. He has been the recipient of many awards including a MERIT award from the NIH and the WICB Senior Recognition award given by the American Society for Cell Biology in recognition of his work supporting the advancement of women in science. Among StahlLab contributions are the discovery of the lysosomal enzyme clearance pathway now implemented in the treatment of lysosomal storage disease, discovery of the innate immune receptor, the mannose receptor, discovery of the exosome secretion pathway, and the role of Rab5 and Arf6 in endocytosis.

Currently his research focuses on endocytosis, signal transduction, and exosome biogenesis and secretion.

VOLUME EDITORS

Gerald Hart is the Director and DeLamar Professor of Biological Chemistry at Johns Hopkins Medical School. He began his research on glycoconjugates about 40 years ago as a graduate student, and he has been active in the field of Glycobiology ever since. Among his research accomplishments, he determined the minimal sequence requirements for N-linked glycosylation while a postdoc in William Lennarz's lab, and he collaborated with Paul Englund's group at Johns Hopkins to elucidate the biosynthetic pathway for GPI-anchors. In the early 1980s, while probing cells with glycosyltransferases, Hart's laboratory discovered cytoplasmic and nuclear protein glycosylation by O-linked N-acetylglucosamine (O-GlcNAc) (e.g., *Journal of Biological Chemistry* 259: 3308; *Journal of Biological Chemistry* 261: 8049). Since that time, the Hart laboratory has published nearly 200 papers on O-GlcNAcylation, identifying and cloning the enzymes controlling cycling, characterizing O-GlcNAcylation and its interplay with phosphorylation on hundreds of proteins, and they have developed many of the tools and methods in use today to study this modification. In

1989, Hart founded the leading journal in the field, *Glycobiology*, serving as Editor-in-Chief until 2001. Hart received the first International Glycoconjugate Organization (IGO) Award in 1997, the Karl Meyer Award from the Society for Glycobiology in 2006, and served as the 2009–2011 president of the IGO. Hart is currently an Associate Editor for *The Journal of Biological Chemistry* and an Associate Editor for *Molecular and Cellular Proteomics*. To date, Hart has published about 263 papers, all in the area of glycosciences. H factor=84.

Bruno Goud studied biochemistry and immunology at the Ecole Normale Supérieure de Cachan and the University of Paris. He received his PhD in 1981 under the mentorship of Jean-Claude Antoine and Stratis Avramias at Institut Pasteur and did postdoctoral work under the mentorship of Peter Novick at Yale University. In 1995, he established an independent research group in the Department of Cell Biology at the Institut Curie in Paris. The main focus of his studies is the regulation of intracellular transport and membrane trafficking in eukaryotic cells. In particular, his group is working on the functions of Rab GTPases, the mechanisms that sustain the global organization of intracellular compartments and the functions of myosins in membrane traffic. Since 2000, he has also developed original *in vitro* approaches to unravel physical parameters such as membrane tension or membrane curvature that underlie transport processes.

Bruno Goud is a recipient of an ERC (European Research Council) Advanced grant (2013). He is a member of the European Molecular Biology Organization (EMBO). He has been the Head of the Department of Cell Biology of Institut Curie since 2003.

Graça Raposo received her PhD in 1989 in Membrane Biology and Immunology at the University of Paris VII where she specialized in electron microscopy and membrane biology. From 1990 to 1995 she was a postdoctoral fellow at the Immunology Center in Marseille and then in the Department of Cell Biology, Utrecht University, The Netherlands. She is the deputy Director of the Department of Cell Biology at Institut Curie and Director of the Training unit. Her major research interests focus on the biogenesis and functions of exosomes and lysosome related organelles with implications in neurodegenerative disorders, lysosomal diseases, and cancer. Her group have started to unravel the cellular and molecular mechanisms regulating the biogenesis of melanosomes, the lysosome related organelles of epidermal melanocytes, studies that open a new avenue to modulate pigmentation in health and disease. In 2012 she was awarded the CNRS Silver Medal and in 2013 the Descartes Huygens Price from the Royal Dutch Academy of Sciences. She is a member of the European Molecular Biology Organization (EMBO).

Alan Ezekowitz, MBChB, DPhil, FAAP, is Co-Founder, President, and CEO of Abide Therapeutics, a company cofounded by Professors Dale Boger and Ben Cravatt from the Scripps Research Institute. He was previously Senior Vice President and Franchise Head, Bone, Respiratory, Immunology, Endocrine, Dermatology and Urology at Merck Research Laboratories. At Merck, he was responsible for the overall scientific direction of the drug discovery and development process. Prior to Merck, Dr. Ezekowitz was Chief of Pediatric Services at the Massachusetts General Hospital for Children and the Partners Healthcare System and the Charles Wilder Professor of Pediatrics at the Harvard Medical School. He chaired the committee that led to the establishment of the Academy at the Harvard Medical School where he served as a Scholar and Founding member. He served on the Board of Directors of the Partners Healthcare System and Massachusetts General Physicians Organization. In 2008 he was honored with the establishment R. Alan Ezekowitz Professorship in Pediatrics at the Harvard Medical School.

He is a member of the American Society of Clinical Investigation, the Association of American Physicians, the American Pediatric Society, and a Fellow of AAAS. He served on NIH Subcommittees on Biodefense and Vaccine Adjuvants; NAS panels on antibiotic resistance and academic pharmaceutical partnerships; and the ARISE 2 task force of American Academy of Arts & Science that is evaluating the impact of federal and industrial funding of science, engineering, and medicine on American universities.

Dr. Ezekowitz received his MBChB and DPhil from University of Cape Town and Oxford University, respectively. At Children's Hospital in Boston, he was a postdoctoral fellow in the Division of Hematology and Oncology with clinical training in pediatrics. He was on the staff of the Children's Hospital of Boston prior to moving to the Massachusetts General Hospital.

He is a pioneer in the field of innate immunity and has over 150 publications. In particular his group played a major role in defining the structure function of the mannose binding lectin and the macrophage mannose receptor.

Douglas A. Lauffenburger is Ford Professor of Bioengineering, and cofounder and Head of the Department of Biological Engineering at MIT, with affiliate appointment in the Department of Biology; he was a founding codirector of the MIT Computational and Systems Biology Initiative in 2002. His major research interests are in cell engineering, with central focus on cell-cell communication and intracellular signal transduction, emphasizing predictive computational models derived from quantitative experiment. Lauffenburger has coauthored a monograph entitled *Receptors: Models for Binding, Trafficking & Signaling* (Oxford University Press, 1993), has coedited the book entitled *Systems Biomedicine: Concepts and Perspectives* (Elsevier, 2010), and has supervised more than 100 doctoral and post-doctoral students. He is a member of the National Academy of Engineering and the American Academy of Arts and Sciences, and has served as President of the Biomedical Engineering Society, Chair of the AIMBE College of Fellows, and on the NIH NIGMS Advisory Council, and coauthored the NRC report on *A New Biology for the 21st Century*.

SECTION EDITORS

Kenneth E Neet received his PhD in Biochemistry in 1965 (with Dr. Frank W. Putnam) from the University of Florida. He was a postdoctoral fellow at the University of California, Berkeley (with Dr. Daniel E. Koshland, Jr.), and joined the faculty of Case Western Reserve University (CWRU) in 1967 as an Assistant Professor of Biochemistry.

Dr. Neet received a Faculty Research Award of the American Cancer Society from 1968 to 1973 and was on sabbatical leave at the National Institute for Medical Research, Mill Hill, England (with Dr. N. Michael Green) 1973–1974. From 1978 to 1990, he was Professor of Biochemistry at CWRU. During 1980–1981, he took a sabbatical year as a Josiah Macy Faculty Scholar in the Department of Neurobiology, Stanford University (with Dr. Eric M. Shooter).

Dr. Neet moved to Rosalind Franklin University of Medicine and Science/The Chicago Medical School in 1990 and was Professor and Chair of Biochemistry & Molecular Biology until 2005. Dr. Neet became Associate Dean for Research of the Chicago Medical School, RFUMS in 2004.

Dr. Neet has served on the Editorial Boards of the *Journal of Biological Chemistry*, *Protein Science*, and *Molecular & Cellular Proteomics* and as a member of study sections for the National Institutes of Health and the National Science Foundation. He was an Associate Editor of the *Journal of Biological Chemistry* (1996–2013).

Dr. Neet's research interests have been in the general areas of protein–protein interactions, allosteric interactions, protein conformational changes, and cell signaling. In his earlier years he studied theoretical and experimental aspects of slow transitions in enzymes, particularly the cooperativity of the monomeric enzyme glucokinase. Later, he studied ligand–receptor interactions of nerve growth factor, establishing a mutational system to study the interactions with its receptors (TrkA and p75), and ultimately the complex signaling emanating from these receptors within neuronal systems.

Sarah A Woodson is a biophysical chemist interested in how RNA molecules fold into specific three-dimensional structures and how they interact with proteins to turn genes on and off in the cell. She was born in Michigan, USA, and attended Kalamazoo College before receiving her PhD in Biophysical Chemistry from Yale University in 1987. After postdoctoral research in the laboratory of Tom Cech at the University of Colorado Boulder from 1987 to 1990, she joined the faculty of the University of Maryland in 1990 and the faculty of Johns Hopkins University in 1999, where she is currently the T.C. Jenkins Professor of Biophysics. Together with Mark Chance and Michael Brenowitz, she pioneered methods for visualizing how RNA molecules change shape in real time. She served on the board of the RNA Society and was elected an AAAS Fellow in 2011 and a Pew Scholar in the Biomedical Sciences in 1993. She is currently a reviewing editor of *Biopolymers* and *Journal of Molecular Biology* and serves on the editorial boards of *Nucleic Acids Research* and *RNA*.

Judith Bond, Evan Pugh Emeritus Professor of Biochemistry and Molecular Biology at the Pennsylvania State University College of Medicine, was President of the Federation of American Societies for Experimental Biology (2012–13) and an Associate Editor of the *Journal of Biological Chemistry* (1999–2013). She received her BS degree from Bennington College in Vermont, her PhD from Rutgers University, and did postdoctoral research at Vanderbilt University. She rose through the academic ranks at the Medical College of Virginia, Virginia Commonwealth University, became Professor and Head of Biochemistry and Nutrition at Virginia Polytechnic Institute and State University, and served at Penn State University College of Medicine as Professor and Chair of Biochemistry and Molecular Biology from 1992 to 2012. At Penn State, she also served as assistant dean for graduate studies, codirector of the All-University Interdisciplinary Biological Sciences Program and founding director of the Medical Scientist Training Program. She recently directed NIH-funded summer research programs for high school students and teachers and for undergraduate students (particularly underrepresented minority groups). Her work on metalloproteases has been funded continuously by the NIH for over 35 years. She has

trained 5 Master's, 21 PhD students, and 19 postdoctoral trainees. Her professional service included member and chair National Institutes of Health Study Sections, member of the National Institute of Diabetes, Digestive and Kidney Diseases Advisory Council, member of the American Association of Medical Colleges – Howard Hughes Medical Institute Committee on the Scientific Foundations for Future Physicians, and President of the American Society for Biochemistry and Molecular Biology.

Elliot Elson received his AB at Harvard, his PhD at Stanford under the mentorship of R.L. Baldwin and did postdoctoral work at University of California, San Diego, under Bruno Zimm. His first independent faculty position was in the Department of Chemistry, Cornell University, where he stayed for 11 years. He then moved to the Department of Biological Chemistry (now the Department of Biochemistry and Molecular Biophysics) at Washington University in St. Louis, School of Medicine. He has pursued research in several biophysical areas. One of these is the development of Fluorescence Correlation Spectroscopy and Fluorescence Photobleaching Recovery and their application to studies of diffusion in cell membranes and of phase separation in model membrane bilayers as well as of other cellular and noncellular phenomena. He has also worked in the areas of cell mechanics, cell motility, and the mechanical properties of engineered tissues. His laboratory has developed approaches for measuring mechanical properties of cells in monolayer culture and for determining the contributions of cells and extracellular matrix to the mechanics of engineered heart and connective tissue constructs.

Tamotsu Yoshimori received his PhD degree in 1989 at Osaka University. After working at several places including European Molecular Biology Laboratory (Prof. Kai Simons' lab) and National Institute of Basic Biology (Prof. Yoshinori Ohsumi's lab), he is now a distinguished professor of Osaka University (Graduate School of Medicine and of Frontier Biosciences). His research interests are focused on intracellular membrane trafficking, and especially for the last 18 years, on autophagy. He identified LC3 as an autophagosome-binding protein, which has been widely used as the gold standard in autophagy assays. The paper has been cited over 3000 times. He also provided new insights into membrane biogenesis in autophagy and the role of autophagy in pathogen defense and suppression of various diseases. He authored or coauthored over 220 journal articles and book chapters. He is an editor of *Journal Cell Science*, and on the editorial board of *Journal of Cell Biology*, *Molecular Biology of the Cell*, and so on. He is a member of the Faculty of 1000 and a vice president of Japan Society for Cell Biology. He was awarded Osaka University Presidential Award for 2012 and 2013, Prize for Science and Technology by the Minister of Education, Culture, Sports, Science and Technology in 2013, Kakiuchi Saburo Memorial Prize by the Japanese Biochemical Society in 2014, and selected as Highly Cited Researchers 2014 by Thomson Reuters.

Paul A Gleeson is currently Head of the Department of Biochemistry and Molecular Biology at the University of Melbourne, located at Bio21 Institute. His research interests include the molecular mechanisms of intracellular membrane transport and the molecular basis of organ-specific autoimmune diseases. Paul Gleeson obtained his PhD in 1980 from the University of Melbourne and did postdoctoral research in the biosynthesis and function of glycoproteins at the Hospital for Sick Children, Toronto, National Institute for Medical research, Mill Hill London and Department of Biochemistry, La Trobe University, Melbourne. He established an independent laboratory at Monash University in 1986 where he defined the targeting signals of Golgi glycosyltransferases, identified golgins of the *trans*-Golgi network and along with his colleagues developed mouse models of autoimmune gastritis. In 2001 he moved to Department of Biochemistry and Molecular Biology at the University of Melbourne and has been Head of the Department since 2006. He has a number of international research collaborations and has been a visiting scientist at the EMBL, Heidelberg, and the Institut Curie, Paris.

Anna Akhmanova studied biochemistry and molecular biology at the Moscow State University. She received her PhD in 1997 at the University of Nijmegen, the Netherlands. She worked as a postdoc at the Department of Microbiology and Evolutionary Biology at the University of Nijmegen and at the Department of Cell Biology at the Erasmus Medical Center in Rotterdam, the Netherlands. In 2001, she started her own research group at the Erasmus Medical Center. Since 2011, Anna Akhmanova is professor of Cell Biology at Utrecht University, the Netherlands.

Akhmanova studies cytoskeletal organization and trafficking processes, which contribute to cell polarization, differentiation, vertebrate development, and human disease. The main focus of her studies is the microtubule cytoskeleton. Her group has described key interactions between proteins associated with microtubule ends and determined their role in the regulation of microtubule organization and dynamics. She has also characterized mechanisms of bidirectional microtubule-based motility of membrane organelles such as cell nuclei and exocytotic vesicles. Her research relies on combining high-resolution live cell imaging and quantitative analysis of cytoskeletal remodeling, measurement of protein dy-

namics using advanced microscopic assays, *in vitro* reconstitution of dynamic cytoskeleton-based processes and different methods of identification of protein-protein interactions.

Anna Akhmanova is a recipient of the ALW Vernieuwingsimpuls VIDI (2001) and VICI awards (2007) (Netherlands Organization for Scientific Research), and an ERC Synergy grant (2013). She is the Chair of the board of the Netherlands Microscopy Society and a member of the European Molecular Biology Organization (EMBO).

Yosef (Yossi) Yarden is a Professor in the Department of Biological Regulation at Weizmann Institute of Science (Rehovot, Israel). Dr. Yarden obtained his PhD from Weizmann Institute (under the mentoring of Dr. Joseph Schlessinger) and later trained at both Genentech Inc., with Dr. Axel Ullrich, and at the Whitehead Institute (MIT), with Dr. Robert A. Weinberg. His group studies the roles played by growth factors and their receptors in cancer progression. They also explore strategies able to intercept growth factor signals in tumors.

Jason D Weber is an Associate Professor in the Departments of Internal Medicine and Cell Biology and Physiology at Washington University and is the Coleader of the Breast Cancer Research Program in the Siteman Comprehensive Cancer Center. Dr. Weber obtained his PhD from Saint Louis University and received postdoctoral training under the mentoring of Dr. Charles J. Sherr at St. Jude Children's Research Hospital in Memphis, TN. His group studies the molecular interplay between oncogenes and tumor suppressors, particularly focused on their role in regulating cellular growth processes.

Michael Dustin received his PhD in 1990 in Cell and Developmental Biology from Harvard University, where he worked in the laboratory of Timothy A. Springer, PhD. During his graduate work he was involved in the identification and cloning of ICAM-1 and ICAM-2, key ligands for the integrin LFA-1. He further demonstrated that LFA-1 dependent adhesion was stimulated by T cell receptor signaling. He did his postdoctoral training with Stuart Kornfeld at Washington University School of Medicine in St. Louis, focusing on mechanisms of lysosome biogenesis. He started his independent lab also at Washington University School of Medicine, and used supported lipid bilayers to define the first protein to modulate organization of the immunological synapse- CD2 associated protein- and the dynamics of immunological synapse formation. He moved to NYU School of Medicine in 2001 where he applied *in vivo* microscopy to tolerance induction and immune responses in effector sites including the liver, brain, and spleen. Continued work with the immunological synapse model resulted in discovery of signaling microclusters, the molecular basis of immunological synapse stability, and the direct budding of extracellular microvesicle enriched in T cell receptors in the immunological synapse. Professor Dustin recently took a position at the

University of Oxford with support of a Wellcome Trust Principal Research Fellowship. The focus of his new post is the translation of the immunological synapse. He received a Presidential Early Career Award in Science and Engineering and the DART-NYU Biotechnology Achievement Award.

David Sassoon directs a research team at Paris Sorbonne. He received his PhD from Columbia University (NYC, USA) in 1986 in the biological sciences and was a professor at Boston University Medical School and Mt. Sinai Medical School before relocating to Paris in 2006. His long-standing interests are in developmental and stem cell biology in a number of tissues including skeletal muscle, skin, CNS, and heart. Dr. Sassoon recently concluded the coordination of a EC-funded 15 partner international consortium (Endostem) designed to identify novel therapeutics for mobilizing endogenous stem/progenitor cells (<http://www.endostem.eu/>) and is a recent recipient as coordinator of a multipartner Transatlantic Network of Excellence grant from the Fondation Leducq focused on cardiac stem cell biology (<http://www.fondationleducq.org/nivel2.aspx?idsec=1360>).

A major focus of his research is on adult progenitor/stem cell biology and how these cells respond to stress. His team has identified a parentally imprinted gene, PW1/Peg3, which is involved in both p53 and inflammatory responses. PW1 is expressed in adult stem cells in all tissues identified to date. Loss of PW1 function in stem cells results in a loss of stem cell competence including a reduced capacity to undergo self-renewal and respond to hypoxic stress. We are currently evaluating a role for PW1 in postnatal and adult heart with a particular focus on its role in vessel precursors using both myocardial infarction and stress-induced myocardial hypertrophy.

Jason M Haugh is a Professor of Chemical and Biomolecular Engineering at North Carolina State University in Raleigh, NC, USA, where he has been on the faculty since 2000. His laboratory has been among those to pioneer the synthesis of quantitative experiments and modeling to study signal transduction in mammalian cells. Since the lab's inception, their approach has combined biochemical measurements, live-cell fluorescence microscopy, and computational modeling to elucidate signaling mechanisms by analyzing their kinetics and spatial organization in cells. The systems studied by the Haugh Laboratory include: regulation of the phosphoinositide 3-kinase, Ras/extracellular signal-regulated kinase, and phospholipase C pathways mediated by receptor tyrosine kinases, and cross talk between these pathways; dynamic organization of multimolecular complexes at cell membranes; signaling mediated by cytokine and chemokine receptors in immune cells; and integration of adhesion, signaling, and cytoskeletal dynamics that direct cell migration.

After graduating with an MA in Mathematics from the University of Cambridge, Helen Mary Byrne received her Master of Science and DPhil from the University of Oxford. She worked as a postdoctoral researcher at the Universities of Oxford and Bath, before taking up a lectureship at the UMIST in Manchester. She moved to the University of Nottingham in 1998 and was awarded a prestigious Advanced Research Fellowship from the United Kingdom's Engineering and Physical Sciences Research Council (2000–2006). She was promoted to Reader in 2002 and Professor in 2003. While in Nottingham, she established and then led the Centre for Mathematical Medicine and Biology until she returned to Oxford in 2011 where she is now based in the Mathematical Institute at the University of Oxford. She has over 20 years' experience of developing, analyzing, and simulating continuum and multiscale models of biomedical systems, and a particular interest in studying the growth and response to treatment of solid tumors.

Rune Linding completed his PhD at the European Molecular Biology Laboratory (EMBL) in Heidelberg, Germany, followed by postdoctoral training at EMBL. He then jointly trained with professors Tony Pawson and Mike Yaffe at the Lunenfeld at Mount Sinai Hospital in Toronto, Canada, and the Massachusetts Institute of Technology (MIT) in Cambridge, US, respectively. Dr. Linding then established his own laboratory of Cellular and Molecular Logic at the Institute of Cancer Research (ICR) in London, UK, before returning to Denmark to take a position as professor of cellular signal integration at the Technical University of Denmark. In 2014, Dr. Linding moved his laboratory to the Biotech Research and Innovation Centre (BRIC) at University of Copenhagen where he is currently professor of cellular signaling. His research group focuses on big data network biology, exploring biological systems by developing and deploying algorithms aimed to predict cell behavior, in particular looking at cellular signal processing and decision making. A strategic focus is to continue to develop computational tools (such as KinomeExplorer, NetworKIN, and NetPhorest) and to deploy these on genome-scale quantitative data obtained by, for example, mass spectrometry, genomic, and phenotypic screens to understand the principles of how spatio and temporal assembly of mammalian signaling networks transmit and process information at a systems level in order to alter cell behavior. His overarching aim is to advance network

medicine by identifying and targeting signaling networks associated with complex diseases. To this end Dr. Linding is currently leading high-level, strategic, multidisciplinary studies of signaling network dynamics driving cancer metastasis in collaboration with other labs at Harvard, Yale, The Jackson Laboratory, Memorial Sloan Kettering Cancer Center, MIT, and BRIC.

CONTENTS OF VOLUME 2

Preface	xxv
Cell Biology: An Overview <i>RA Bradshaw and PD Stahl</i>	xxvii

VOLUME 2 Organizational Cell Biology

Organizational Cell Biology: An Overview <i>EL Elson, G Raposo, PA Gleeson, A Akhmanova, T Yoshimori, PD Stahl, and B Goud</i>	1
--	---

Imaging the Cell

Electron Microscopy

Single-Particle CryoEM of Macromolecular Complexes <i>J Zhang, KV Gorzelnik, MF Schmid, and W Chiu</i>	5
Scanning Electron Microscopy in Cell Biology <i>TD Allen and MW Goldberg</i>	14
Electron Tomography <i>T Ishikawa</i>	22
Immunoelectron Microscopy: High-Resolution Immunocytochemistry <i>W Möbius</i>	32
Imaging Cellular Architecture with 3D SEM <i>LM Hartnell, LA Earl, D Bliss, A Moran, and S Subramaniam</i>	44

Light Microscopy

Genetically Encoded Fluorescent Probes and Live Cell Imaging <i>GRV Hammond, CEJ Cheetham, and T Balla</i>	51
Total Internal Reflection Fluorescence Microscopy <i>D Axelrod</i>	62
Super Resolution Fluorescence Localization Microscopy <i>MJ Mlodzianoski, MM Valles, and ST Hess</i>	70
Super-Resolution Light Microscopy: Stimulated Emission Depletion and Ground-State Depletion <i>Y Wu, X Wu, R Lu, M Li, L Toro, and E Stefani</i>	76
Structured Illumination Microscopy <i>V Mennella</i>	86
Fluorescence Correlation Spectroscopy: A Tool for Measuring Dynamic and Equilibrium Properties of Molecules in Cells <i>EL Elson</i>	99
Fluorescence Lifetime Imaging – Applications and Instrumental Principles <i>W Becker</i>	107
High-Speed Localization Microscopy and Single-Particle Tracking <i>M El Beheiry and M Dahan</i>	121
Intravital Microscopy in Mammalian Organisms: From Tissue Physiology to Cell Biology <i>R Weigert</i>	129
Optogenetics <i>EY Isacoff and A Reiner</i>	147

Organelles

Structure and Function

The Endoplasmic Reticulum	<i>E van Anken and R Sitia</i>	156
Intermediate Compartment: A Sorting Station between the Endoplasmic Reticulum and the Golgi Apparatus	<i>J Saraste and M Marie</i>	168
Golgi and TGN	<i>A Luini and S Parashuraman</i>	183
Early Endosomal Compartments	<i>P van der Sluijs</i>	192
The Late Endosome	<i>F Vacca, C Scott, and J Gruenberg</i>	201
Signaling from Endosomes	<i>J Alanko, H Hamidi, and J Ivaska</i>	211
Conventional and Secretory Lysosomes	<i>R Shrestha, J Kaplan, and DM Ward</i>	225
Lysosome-Related Organelles	<i>M Fukuda</i>	235
At the Center of Autophagy: Autophagosomes	<i>F Reggiori and M Mauthe</i>	243
Peroxisomes	<i>PB Lazarow</i>	248
Lipid Droplets	<i>C Thiele and A Penno</i>	273
Mechanisms and Functions of Mitochondrial Dynamics	<i>K Mihara and H Otera</i>	279
Synaptosomes and Synaptic Vesicles	<i>JC Trinidad</i>	293
Extracellular Vesicles	<i>MHM Wauben</i>	302
Nuclear Organization (Nuclear Structure and Dynamics)	<i>Y Mimura and N Imamoto</i>	311
Nuclear Pores	<i>M Oka and Y Yoneda</i>	319
Plastids: The Anabolic Factories of Plant Cells	<i>RR Wise</i>	324

Interorganellar Communication

Interplay and Processes

ER–Golgi Transport	<i>S Pagant and EA Miller</i>	331
N-Linked Glycans (N-Glycans)	<i>P Stanley</i>	339
Extracellular O-Glycans	<i>KG Ten Hagen and L Zhang</i>	347
Intra-Golgi Transport	<i>A Aguilera Gomez and C Rabouille</i>	354
Post-Golgi Transport – Cargo, Carriers, and Pathways	<i>JL Stow and RZ Murray</i>	363
Regulation of the Secretory Pathway	<i>A Capalbo, J Cancino, and A Luini</i>	371
Regulated versus Constitutive Secretion – A Major Form of Intercellular Communication	<i>J Stöckli, RC Piper, and DE James</i>	376
Clathrin and Clathrin-Dependent Endocytosis	<i>FM Brodsky</i>	384
Clathrin Independent Endocytosis	<i>RG Parton</i>	394
Rabs of the Endosomal Recycling Pathway	<i>AJ Lindsay and MW McCaffrey</i>	401
Endosome to Lysosome Transport	<i>C Bucci and M Stasi</i>	408
Endocytosis of Cargo Proteins: LDL	<i>LM Traub</i>	418
Retrograde Transport	<i>L Johannes and C Wunder</i>	433

Rabs and Other G Proteins	<i>G Li</i>	442
Components		
Adaptor Proteins: Inter-Organelle Traffic Controllers	<i>K Madhivanan, W-C Hsieh, and RC Aguilar</i>	450
SNAREs: Membrane Fusion and Beyond	<i>T Galli and D Tareste</i>	459
ESCRTing around the Cell	<i>PI Hanson and CE Jackson</i>	466
The Retromer Complex	<i>MNJ Seaman</i>	475
Vesicle Tethers	<i>LL Marcotte and M Munson</i>	485
BAR Domains and BAR Domain Superfamily Proteins	<i>M Sharma and S Caplan</i>	491
Interplay and Processes		
Role of Phosphoinositides in Membrane Traffic	<i>DA Sheffield, R Gurung, and CA Mitchell</i>	503
Unconventional Protein Secretion: Fibroblast Growth Factor 2 and Interleukin-1 β as Examples	<i>W Nickel, JP Steringer, H-M Müller, and D Brough</i>	520
Endoplasmic Reticulum Stress in Disease	<i>RJ Kaufman and L Popolo</i>	528
Cytoskeleton and Motors		
Cytoskeletal Components		
Microtubules and Microtubule-Associated Proteins (MAPs)	<i>A Straube</i>	539
Actin Assembly Dynamics and Its Regulation in Motile and Morphogenetic Processes	<i>J Pernier, P Montaville, and M-F Carlier</i>	548
Intermediate Filaments	<i>RE Leube and N Schwarz</i>	569
Septins: Cytoskeletal Filaments with Structural and Regulatory Functions	<i>ET Spiliotis and L Dolat</i>	579
Bacterial and Archaeal Cytoskeletons	<i>D Ghosal, J Löwe, and LA Amos</i>	588
Myosins	<i>SM Heissler and JR Sellers</i>	597
Kinesin Superfamily Proteins (KIFs) as a Fundamental Component of Life: Intracellular Transport and Beyond	<i>Y Tanaka and N Hirokawa</i>	608
Dyneins	<i>CA Cypranowska, A Yildiz, and T Ishikawa</i>	620
Complex Cytoskeletal Structures		
The Mitotic Spindle	<i>M Barisic and H Maiato</i>	637
Centrioles and the Centrosome	<i>J Sillibourne and M Bornens</i>	649
Cilia and Flagella	<i>F Schmid, ST Christensen, and LB Pedersen</i>	660
Skeletal Muscle	<i>B Cadot and ER Gomes</i>	677
Filopodia and Lamellipodia	<i>TM Svitkina</i>	683
The Extracellular Matrix	<i>AD Bradshaw</i>	694
Cell–Cell Adhesion and the Cytoskeleton	<i>BR Acharya and AS Yap</i>	704
Cell Adhesion to the Extracellular Matrix	<i>B Geiger and A Livne</i>	713

Cell Migration	<i>A Ortega-Carrion, L Feo-Lucas, and M Vicente-Manzanares</i>	720
Rho GTPases	<i>MJ Lukey and RA Cerione</i>	731
Cell Polarity	<i>F Martin-Belmonte, I Bernascone, and M Galvez-Santisteban</i>	741

Intracellular Infectiology

Cell Processes

Phagocytosis	<i>F Niedergang</i>	751
Macropinocytosis	<i>JA Swanson and S Yoshida</i>	758
Microbicidal Mechanisms	<i>L-AH Allen</i>	766
Bacterial Subversion of Phagocytic Killing	<i>RR Isberg, S Asrat, DA de Jesús, AD Hempstead, and V Ramabhadran</i>	776
Cellular Invasion by Bacterial Pathogens	<i>ML Ferrari and PJ Sansonetti</i>	784

Infectious Agents

Bacterial Protein Toxins as Tools in Cell Biology and Physiology	<i>M Rigoni and C Montecucco</i>	794
The Gut Microbiome	<i>H Neuman and O Koren</i>	799
Cell Biology of Virus Infection	<i>A Helenius and Y Yamauchi</i>	809
Virus Factories and Mini-Organelles Generated for Virus Replication	<i>T Wileman, CL Netherton, and PP Powell</i>	819
HIV – The Cell Biology of Virus Infection and Replication	<i>S Giese, A Pelchen-Matthews, and M Marsh</i>	828
Prions	<i>G Legname and KE Pischke</i>	839

Cell Processes

Cellular Responses to Infections in <i>Caenorhabditis elegans</i>	<i>J Sun, A Aballay, and V Singh</i>	845
---	--------------------------------------	-----

PREFACE

Cell biology is the study of cells, the integral unit that is the basis of all living tissues. In its earliest phases, this area of investigation was largely defined by microscopic-based observations of structure and organization that were, by their nature, largely descriptive. This also served to delineate cell biology from its nearest neighbor, biochemistry, which, dating from its post WWII renaissance, was driven in large part by reductionist approaches, where tissues, cells, and organelles were broken down in order to isolate and then characterize individual components. The melding force that bridged these two areas was molecular biology that allowed the cell biologist to transform pictures into functions and allowed the biochemist to reassemble their components into ensembles and subcellular entities. Not surprisingly the boundary between these two key biological sciences has become blurred beyond recognition. Today a considerable part of what passes as cell biology is by any other name biochemistry (or molecular biology – the distinction between these two areas being equally indistinct) and vice versa. Indeed, one of the first challenges we faced in organizing this Encyclopedia was how much molecular detail to include. It was our conclusion that for the sake of completeness, and to appropriately introduce the sections Organizational Cell Biology and Functional Cell Biology, we needed a description of the molecular components of the cell, particularly with respect to the synthesis and degradation of proteins and nucleic acids, along with outlines of important chemical principles and key methodology. We were guided to some degree in these decisions by input from undergraduate and graduate teachers and the contents of their introductory courses that they shared with us and by discussions with our section and subsection editors. The result was the first section, which we recognize is very 'biochemical,' but certainly lacking the more detailed coverage of the *Encyclopedia of Biological Chemistry* (Lennarz and Lane, 2004) or the many excellent biochemical texts that dot the educational landscape. Readers who find 'gaps' or incomplete treatments in this section will likely be able to find the additional detail they seek from these sources.

The second major decision that we had to confront was whether we would attempt to cover the full range of living organisms or whether we would place some limits on the scope of the material we included. In the final result, it was decided to place the emphasis on higher eukaryotes with only very prescribed treatments of lower eukaryotes and prokaryotes. Sections 2 and 3 thus deal with material that has perhaps been more traditionally thought of as cell biology. Again we were guided in our decisions about what to include by teaching considerations, brainstorming sessions with our editors, and a perceived need to separate cellular organization from cellular function. However, as even a quick perusal will reveal, this is not a sharp delineation either. Section 2 begins with a methodological treatment of imaging, which is basically divided between light and electron microscopic applications, and is followed by sections on organelles, interorganellar communication, and the cytoskeleton (including motors). The

last part of section 2 is devoted to intracellular infection and covers a variety of external agents and pathogens that impact cell function as well as human pathology. Section 3, in contrast, largely deals with major cell functions: signaling, cell-cycle control, and apoptosis. The last two parts are devoted to cells of the immune system and their responses and stem cells – two highly specialized niches characterized by unique cellular involvement.

The last part of the Encyclopedia deals with systems biology. This is really the newest area of cell biology and considers cellular involvement as part of a phenotypic response. As such, it strives to integrate all of the levels of the first three sections in a consistent manner to produce a seamless description of cellular function. This is clearly a newly evolving area and the most rapidly changing part of cell biology; indeed it is where we expect to see the greatest change in the next few years.

Assembling a treatment of a topic as large as cell biology had multiple challenges. Coverage was a significant problem: on the one hand it was almost impossible to avoid some redundancy in places while, on the other, there were inevitable gaps. Some of these arose from late cancellations; others from oversights on our part. We can only promise to fill these in future editions. We also note that as can be expected for a large multiauthor compilation the individual articles do differ in detail and treatment. We felt it was more important to allow our experts substantial latitude in deciding how to present their topics than to apply rigid guidelines. We did try to limit the number of references (to make it easier for people not familiar with a topic to make the transition to more extensive articles) but there is admittedly some considerable variation in the bibliographic material as well.

When we were well into the project, we were approached by Graham Nisbet (Elsevier) about including the Encyclopedia in a larger collection entitled the Reference Module in Biomedical Sciences. The Reference Module plan was grouped in single integrated work information from several other compendia and it was our view that this would greatly leverage the value of our efforts (and those of our contributors). While we were the 'new kid on the block' in that we were still compiling the Encyclopedia and the other collections to be included were already extant, we felt that it was too good an opportunity to pass up. The Reference Module has since been launched and although it does not yet contain the complete content from the Encyclopedia, this will be achieved in the not too distant future. We consider that this will be a particularly valuable resource for researchers that are just entering (or changing into) this field.

No work of this size could be completed without the help and advice of many people. In this regard we would like to thank a number of people who were instrumental in bringing this project to fruition. First and foremost we would like to recognize our section editors: Jerry Hart, Graça Raposo, Bruno Goud, Alan Ezekowitz, and Doug Lauffenburger; and our subsection editors: Ken Neet, Sarah Woodson, Judy Bond,

John Heuser, Elliot Elson, Tamotsu Yoshimori, Paul Gleeson, Anna Akhmanova, Yosef Yarden, Jason Weber, Michael Dustin, David Sassoon, Jason Haugh, Helen Byrne, and Rune Linding; and thank them for their invaluable input, enthusiasm, and hard work. They are truly a global group and have been a great team to work with. We also wish to thank the staff at Elsevier including Janice Audet, Peter Labella, Nicky Carter, Karen Maloney, Erin Hill-Parks, Rashmi Phadnis, Blerina Osmanaj, and Ginny Mills for their many efforts, perseverance (particularly with our idiosyncrasies), and skillful management of every aspect of this project.

In the course of planning this work, we gathered information from a number of sources. At the outset the publishers polled some 167 faculty from both undergraduate and graduate schools to ascertain their perceived interest in such a project, which also garnered considerable input about potential topics. The response was highly favorable. We also talked with many colleagues about experiences at their institutions and would like to particularly thank Catherine Bevier (Colby College), Robert Simoni (Stanford University), Larry Marsh (UC Irvine), and John Cooper (Washington University) for providing syllabi of germane courses taught in their institutions. Special thanks also go to Ruedi Abersold (ETH, Zurich) and Sergio Grinstein (University of Toronto) for their expertise that they readily shared with us, which was invaluable in planning certain sections.

Finally we would like to recognize all of our authors. We have been extraordinarily fortunate in attracting individuals from all around the globe to take time from their busy schedules to prepare this splendid set of contributions. Without these efforts there would be no Encyclopedia. Under ordinary circumstances it would be appropriate to dedicate the work to them and all the colleagues whose works they wrote about. However, during the preparation of this work, we sadly lost one of the most important contributors to cell biology, Tony Pawson. Tony was a true pioneer in elucidating basic mechanisms of how cells transmit information intracellularly, a fundamental knowledge that permeates all of cell biology. In an effort that was initiated by one of the subsection editors, Rune Linding, it was decided to dedicate the entire work to his memory as recognition of his contributions and a lasting tribute to a man who left us too soon.

We hope that the Encyclopedia will be of value to students and researchers alike and will become a useful tool in the training of future generations of scientists.

Ralph A Bradshaw and Philip D Stahl

All living organisms can be divided into three principal categories: archaeobacteria, eubacteria, and eukaryotes; although they differ in structure and organization, they are all composed of cells as the fundamental life unit. At the molecular level, there is also a great deal of similarity in the basic materials that make up these entities because they use the same kinds of molecules to store and reproduce information, to run the cellular metabolism and machinery and to provide the structural framework. Thus nucleic acids, proteins, lipid membranes, and carbohydrates – alone and in various combinations – are universally present, albeit in distinguishable forms, along with innumerable metabolites and ions. There are components that are apparently essential for life and are found in one form or another in all species and there are many unique moieties and associated activities that are highly specialized and are found in relatively few organisms. Indeed, the similarities have underpinned the development of our understanding of cellular function at a rudimentary level and the differences, basically engendered by evolution, have illustrated and delineated the complexity that speciation has introduced. Perhaps the largest of these differences is that which separates single cell organisms from multicellular organisms. The latter are exclusively eukaryotes while the former are composed of both eukaryotes and prokaryotes. The cellular organization and architecture that distinguishes these two major life forms is striking; although cell biology correctly embraces both, traditionally prokaryotic organisms have been the province of the microbiologists and the majority of cell biology research has been devoted to the eukaryotic world. In practical terms this translates for the most part into the study of human cells and those of easily maintained laboratory animals and selected paradigms, for example, fruit flies, worms, and zebra fish.

Human and animal cell biology is not a tightly proscribed science with well-defined borders. Basically it serves at the interface between biochemistry, molecular biology, and genetics, on the one hand, and anatomy and physiology, on the other. The continuum of these disciplines forms the core of the biomedical sciences, which also include the related but separate fields of pharmacology, microbiology, immunology, and pathology that provide the connections to disease and health. Cell biology has strong connections to all of these. There are also specialized areas, for example, neuroscience, that are of such importance that they warrant their own category and the cell biology associated with them is also highly specialized. Thus, cell biology is as complex as the enormous variety of cells that exist and achieving an accurate description of all of them in terms of their components and functions has long been a major part of the research in this field.

Imaging and Organelle Organization

Among the developments that propelled cell biology into the modern era are the introduction of the ultracentrifuge and

the rapid advances in microscopy both electron and light microscopy – the former allowing investigators to fractionate and characterize the components of the cell and the latter to literally see them – either *in situ* or in isolated form. This progress is illustrated by a series of Nobel Prizes starting in the early 1970s that chronicle the grand confluence of classical biochemistry and general physiology that created modern cell biology (Claude *et al.*, 1974) or the discovery and characterization of intracellular organelles – lysosomes and endoplasmic reticulum (ER) among others (Mitchell, 1978), for the chemiosmotic hypothesis (Brown and Goldstein, 1985), for endocytosis (Ciechanover *et al.*, 2004), for ubiquitination and protein degradation, and just recently (Rothman *et al.*, 2013), for vesicle trafficking, and (Betzig *et al.*, 2014) for advances in light microscopy. The early cell biologists insisted on quantitative application of these new techniques and laid the groundwork for modern cell biology. As with biochemistry, reductionism has been the keystone for the amazing success over these past several decades. Each organelle has its own research history – the nucleus, mitochondria, peroxisomes, the proteasome, the ER, and cytoskeleton. The Golgi apparatus/secretory pathway and the endosome–lysosome network have all been examined in detail both in isolation and in their relationships with each other. A new member, the exosome (aka extracellular vesicle) has emerged more recently and stimulated the imagination of aspiring young investigators (Harding *et al.*, 2013). The rise of genomics, the development of spectacular imaging modalities, and evolving biochemical techniques (proteomics) have led to the discovery of molecular motors, the identification of macromolecular complexes such as the exocyst, ESCRT, GARP, SNARES among others that choreograph complex intracellular pathways, including cell motility and cytokinesis, have brought cell biology into this new era where the whole is now seen as larger than the individual components. This creates the segue from Parts 1 and 2 of the *Encyclopedia (Molecular Cell Biology and Organizational Cell Biology)* to Part 3 (*Functional Cell Biology*) where signaling modalities will be seen as an integrative force for regulation and control.

Signaling

While all organisms can sense their environment and respond to cues from it, multicellular organisms must in addition coordinate their responses, which require intercellular communication at a sophisticated level (Bradshaw and Dennis, 2009). The higher the development, the more complex these communication systems become. Thus the cell biologist must focus not only on how molecular function is translated into cell organization and how these functions are coordinated from organelle to organelle but also on the external interactions and signals that control the larger functional responses of organs and ultimately organisms.

Intercellular communication is afforded by stimuli that can be transmitted across the cell membrane, either directly or via membrane bound molecules that in turn pass signals to the intracellular compartment. The origins of these stimuli may be quite diverse. Among other things, they can include cell–cell contacts, soluble factors/messengers, or foreign agents. Lipophilic molecules can cross the membrane by diffusion or by facilitated transport to recognize and bind to intracellular entities but most substances bind to membrane bound proteins and induce their signal by ‘activating’ them instead. These so-called receptors are capable of producing a variety of responses that invariably involve the generation of posttranslational modifications of preexisting proteins. Protein phosphorylation, which in eukaryotes mostly occurs on tyrosine, serine, and threonine residues, is highly prevalent and appears to be directly or indirectly involved in almost all transmembrane signaling (Gnad *et al.*, 2011). However, it is by no means the only vehicle for transmitting information as acetylation, methylation, monoglycosylation, and ubiquitination, to name a few, are both important and widespread. There are over three hundred different covalent modifications (Khoury *et al.*, 2011) that are introduced into proteins (and many more that have not yet been chemically defined) of both a transient and stable nature and most are likely to be involved to some extent in signal transduction processes. In addition, limited proteolysis can also be an important part of a pathway and this activity is a major player in cellular responses (Turk *et al.*, 2012).

The induction of an intracellular signal is basically perpetrated by the formation of new interactions between the modified proteins and other entities, which can range from small molecules to macromolecular protein complexes. One of the most important advances in understanding how cells process information induced from external stimuli was the appreciation that the newly formed sites produced by the protein modifications were recognized by other proteins with modules specifically designed for this purpose (Pawson, 1995). Thus, for example, phosphotyrosine residues could be recognized by other proteins containing a domain, termed SH2 for its relatedness to a similar domain found in the Src protein kinase, which could then be further modified allowing for additional interactions to occur. By these ‘docking’ events, signaling complexes could be assembled, often in multiple steps, that ultimately lead to the activation of key effectors. The end point of many of the pathways is the activation of transcription factors that lead to the modulation of gene expression of that cell by ultimately changing its protein expression profile (Bradshaw and Dennis, 2009). However, many molecules are usually modified and activated ‘along the way’ and these ‘new’ activities also add to the overall response to the original stimuli. Short term responses indeed require that the protein effectors necessary for it are already present; long term responses per force require new protein synthesis.

Signal transduction is thus dependent on two phenomena: posttranslational modifications, particularly of the readily reversible type, and protein–protein interactions. The extent to which these two activities take place, even in resting, unstimulated cells was greatly underestimated before the advent of proteomics and the introduction of mass spectrometric methodology into cell biological research (Bradshaw and

Burlingame, 2005). These high-throughput unbiased analyses of very complex mixtures, basically derived directly from cell lysates, revealed that essentially every protein had multiple interacting partners and that posttranslational modifications affected a very significant proportion of the proteins present. These were profound differences from what had been the prevailing wisdom and amounted to a paradigm shift in thinking about cellular organization and structure. As noted above, these same tools have gone on to cast new light on organelle organization in terms of resident proteins and have helped to disclose the structure of important cellular machines, such as the proteasome (Voges *et al.*, 1999), the nuclear pore (Routa *et al.*, 2000), and transcription complexes (Kornberg, 2007). They have also begun to elucidate the complexity of epigenetic regulation of gene transcription at the histone level (Cosgrove, 2012), which will also be essential in completing our understanding of signaling processes.

Concluding Remarks

Two of the most fundamental aspects of cells are their ability to reproduce themselves and, in higher organisms, to undergo changes that lead to new cell types and functions. These developmental processes leading to differentiation are what allow a single fertilized egg to form a complex adult organism and require the synthesis of all aspects of cell biology to understand. Knowing how cells go from one state to another in a timed and regulated fashion forms the core of developmental biology, which can be viewed as a sub discipline of cell biology. Also of major importance is the maintenance of viability and the associated turnover processes. The control of cell death is not only an essential part of development it is also key to managing situations that have gone awry and underlies many serious disease conditions.

It is clear that science is still a long way from understanding how even simple cells work. There is a long list of functions and structures that remain to be elucidated and integrating the various experimental approaches and the data they produce still lags far behind. This is the ‘Era of Big Data’ and vast amounts of new information that impact on our understanding of cells and their processes are collected every day. Genomic information is a good example – despite the rapidity that this sort of information can now be obtained, it still remains to be effectively mined in terms of what it can tell us about basic principles of how cells work. There has been an understandable pressure to apply this information to managing disease (Collins and Varmus, 2015), particularly those that are life threatening, but there certainly is information that is yet to be formulated that would apply to fundamental problems as well. The same can be said for transcriptomics, proteomics, and metabolomics. In addition to these powerful new technologies, singular advances in analyzing single cells promises to augment these molecular approaches significantly (Di Palma and Bodenmiller, 2015).

One aspect of cell biology that is looking to address the challenges of integrating these relatively newly minted studies is systems biology (Part 4). It is far too early to assess the value of these efforts in coordinating this flood of information but it certainly looks promising. It will be an elusive goal for some

time to come but also a stimulus for new generations of cell biologists that will be forthcoming.

The cell is the building block of life and, as written by [Lewis Wolpert \(1999\)](#), can be considered as the evolution's most magnificent achievement. Cells, in particular animal cells (plants cells being surrounded by a wall that imposes a constraint), display all kinds of shapes and sizes, and many different types are present in the same living organism (for instance, more than 350 types of cells have been described in humans). Besides this huge diversity, all cells share the same fundamental feature, i.e., the capacity to behave as stable functional units. Such remarkable functional stability allows them to resist change over time and to respond to threats. The cell functional stability relies on its organization in compartments or organelles, which are themselves organized in cellular space by the cell cytoskeleton. Still this organization is not static and the development of live cell imaging approaches in the last 20 years has illustrated the extraordinary dynamics of cell compartments and the multiple connections that exist among them. On the other hand, the loss of stability at the cell level leads to a pathological state, a remarkable example being cancer progression. A loss of stability can also be provoked by pathogens and toxins, which in many cases, can subvert cellular functions to their own benefit.

Part II of the Encyclopedia is divided into five sections that describe the range of imaging approaches developed to date to understand the cell organization (see Section Imaging the Cell), the principle organelles (see Section Organelles), the communications between organelles (see Section Inter-organelle Communication), how cell architecture is maintained (see Section Cytoskeleton and Motors), and how cell organization can be altered by pathogens (see Section Intracellular Infection).

Imaging the Cell

The potential of optical methods to acquire a dynamic view of molecules, cells, tissues, and organisms is extraordinary indeed, microscopy is the Dean of Cell Biology. Both light and electron microscopy have moved cell biology into a new era. Yet subcellular structures and organelles, their specific morphological and compositional characteristics, their intimate details and possible connections can be seen only by high-resolution transmission and scanning electron microscopy (TEM and SEM, respectively). TEM has been used for more than 70 years to investigate the ultrastructure of cells and tissues in normal and pathological situations. In more recent times methods have been developed that allow for the analysis of molecular complexes, fine details and 3D analysis of cells,

tissues, small organisms, and subcellular structures including the localization of cellular components with an intraorganelle context. Single-particle cryoEM allows for a near-atomic ($\sim 3\text{--}4\text{ \AA}$) resolution of structures or macromolecular complexes such as virus particles, molecular machineries, and membrane proteins. Importantly, these can be viewed in close to native state, without contrasting agents and after vitrification by Cryo-EM ([Single-Particle CryoEM of Macromolecular Complexes](#)). Scanning EM has a lower resolution than TEM but it is the only method that permits one to delineate the surface of cells and small organisms and to appreciate structural details thanks to its depth of field and three-dimensional (3D) surface imaging characteristics ([Scanning Electron Microscopy in Cell Biology](#)). These classical SEM methods are powerful and have been improved lately by developments in electron microscope technology permitting visualization of isolated organelles and large complexes such as nuclear pores ([Scanning Electron Microscopy in Cell Biology](#)). Unfortunately, they do not provide 3D information on the internal characteristics of cells, tissues, and organisms. Over the past few years this limitation has been surpassed by combining SEM imaging with the use of a microtome or a focused ion beam (FIB) that progressively removes sections from the top of the object under study thus uncovering fine details of the interior structures. The acquired images can be stacked and a 3D model can be generated to appreciate the internal organization of a specimen that may be composed of several cells ([Imaging Cellular Architecture with 3D SEM](#)). In a very complementary manner and with a higher resolution, Electron Tomography allows one to resolve the 3D organization of molecular and subcellular structures by TEM of plastic embedded sections of cells and tissues and Cryo-TEM of unstained, vitrified specimens ([Electron Tomography](#)).

Visualization of molecules within their intracellular and intraorganelle contexts can be achieved using electron dense probes that can be viewed by TEM. Localization methods are most generally based on the recognition of molecules by specific antibodies (Immuno-EM). Such methods combine localization and preservation of ultrastructure and permit discrimination of seemingly identical compartments by their molecular composition in a quantitative manner ([Immuno-electron Microscopy: High-Resolution Immunocytochemistry](#)).

For many years fluorescence has been the dominant optical property used to study structural and functional properties of cells. Its advantageous qualities include chemical selectivity, i.e., the ability to measure specifically labeled molecular species at very low concentration in the presence of high concentrations of unlabeled molecules, relative ease and speed of measurement, high spatial resolution when used with a

confocal or 2-photon fluorescence microscope and, when used judiciously, lack of interference with normal cell function. The articles in this section of the Encyclopedia provide an introduction to methods that exploit recent advances in microscopy and labeling technology that have opened a new golden age of applications of fluorescence to cell biology. Several of the articles describe methods that enable imaging resolution beyond the Abbe/Rayleigh limit in the range of 200–300 nm for visible light. The oldest of these is total internal reflection microscopy (TIRFM) that provides sub-diffraction optical resolution along the optical axis and so has been a mainstay of studies of dynamic processes of single molecules bound to glass substrates. TIRFM does not, however, improve lateral resolution ([Total Internal Reflection Fluorescence Microscopy](#)). Localization methods such as PALM, STORM, and FPALM assemble high-resolution images of macromolecular structures by summing the contributions of component fluorophores whose individual positions are determined with accuracies near 10 nm ([Super Resolution Fluorescence Localization Microscopy](#)). As described in article [Super-Resolution Light Microscopy: Stimulated Emission Depletion and Ground-State Depletion](#), STED microscopy is scanning super-resolution approach based on restricting the radius of the excitation light to sub-diffraction dimensions. STED has the advantage of acquiring fluorescence signals rapidly enough to be useful in studies of dynamic molecular behavior, for example, via fluorescence correlation spectroscopy (FCS). Structured illumination microscopy (SIM) breaks the diffraction limit by imposing a periodic spatial pattern on the excitation light. Although SIM does not match the resolution of STED and localization methods, it has other advantages of flexibility, relative ease of use and high throughput ([Structured Illumination Microscopy](#)). At a higher structural level intravital microscopy ([Intravital Microscopy in Mammalian Organisms: From Tissue Physiology to Cell Biology](#)) is used to investigate tissue and cell architecture in living animals and cells. This method has recently benefitted from applications of molecular genetics and improvements in microscopy and fluorescent probes. Fluorescence lifetimes are sensitive to the environment of the emitting fluorophore. Therefore, fluorescence lifetime imaging microscopy (FLIM) provides a unique and popular method for enhancing the contrast of fluorescence images to reveal regional differences in a variety of cellular properties and functions, for example, metabolism, ionic concentrations, and molecular composition ([Fluorescence Lifetime Imaging – Applications and Instrumental Principles](#)). Optogenetics ([Optogenetics](#)) uses light to trigger molecular functions, and thereby to control activities in living cells. This powerful new approach has mainly been used to control cellular excitability through regulating ion channel function. Although FCS was invented in the 1970s, many variations and extensions have been developed, since then continue to be valuable tools to investigate dynamic molecular processes in cells. The family of FCS and closely related photobleaching (FRAP (fluorescence recovery after photobleaching)) methods yield important information about molecular transport as well as rates and extents of molecular interactions ([Fluorescence Correlation Spectroscopy: A Tool for Measuring Dynamic and Equilibrium Properties of Molecules in Cells](#)). While FCS and FRAP rely on dynamic changes in the numbers of fluorescent molecules

detected within a small measurement area that can be no smaller than the optical resolution limit to measure transport rates, single-particle tracking extended by current localization microscopy methods allows measurement of the trajectories of individual molecules with precision in the range of 10 s of nm ([High-Speed Localization Microscopy and Single-Particle Tracking](#)). This approach allows a unique analysis of the mechanisms of motion of the tracked molecules. Finally, the use of genetically encoded fluorescent probes coupled with live cell imaging opens a window of opportunity to view cellular events in spectacular detail ([Genetically Encoded Fluorescent Probes and Live Cell Imaging](#)).

Organelles

Acquisition of diverse intracellular compartments was truly revolutionary epoch in the long history of cellular evolution. Each compartment, known as an organelle, is enclosed by membrane, meaning that cells have a vast area of membrane surface at their disposal, in addition to the plasma membrane surrounding cells, which can act as a platform for biochemical reactions that sustain cellular activities. In addition, the interior space of organelles (the luminal space) sequestered by their limiting membranes also enables cells to perform distinct reactions efficiently. Indeed, organelles contain their own characteristic set of proteins and other molecules to achieve functions unique to each.

Study of organelles is undoubtedly one of major streams in cell biology, which started when Robert Brown observed a small dark structure inside plant cells and named it ‘nucleus’ in 1831. This seminal discovery was followed by identification (or naming) of mitochondria by C. Benda and the Golgi apparatus by C. Golgi in the same year 1898, and lysosomes by C. de Duve in 1955. An enormous amount of research from these times has revealed the amazing ‘true colors’ of organelles, but we have not yet completely understood their function and structure; study is still ongoing. This section of the encyclopedia comprehensively covers major organelles including recently discovered and cell-type-specific organelles.

Organization of the nucleus, a center for genome storage and for controlling its expression, is introduced in the article [Nuclear Organization \(Nuclear Structure and Dynamics\)](#). There is macromolecular traffic between nucleus and the cytoplasm via the nuclear pore, which is large protein complex inserted into the nuclear double membrane, as discussed in the article [Nuclear Pores](#). Van Anken and Sitia ([The Endoplasmic Reticulum](#)) describe the multifunctions of the endoplasmic reticulum; synthesis of lipids and proteins, Ca^{++} ion storage, signal integration, and interaction with other organelles. Otera and Mihara ([Mechanisms and Functions of Mitochondrial Dynamics](#)) focus on mitochondria dynamics; these cellular power plants are highly dynamic and fusion/fission of their membranes play a pivotal physiological role. Cargo internalized into cells from outside is transferred sequentially along the endocytic pathway consisting of early endosomes ([Early Endosomal Compartments; Endocytosis of Cargo Proteins: LDL](#)), late endosomes ([The Late Endosome](#)), and lysosomes ([Conventional and Secretory Lysosomes](#)). Lysosomes are final destination in the pathway, but can fuse with plasma membrane under certain

conditions (secretory lysosomes), as discussed in the article [Conventional and Secretory Lysosomes](#). In addition, endosomes also function as a platform of signaling, as described in the article [Signaling from Endosomes](#). Membrane traffic from the cytoplasm to lysosomes also exists (the autophagic pathway), which is mediated by autophagosomes ([At the Center of Autophagy: Autophagosomes](#)). On the other hand, lipids and proteins synthesized in the endoplasmic reticulum are transported to the Golgi (Golgi and TGN) via intermediate compartments ([Intermediate Compartment: A Sorting Station between the Endoplasmic Reticulum and the Golgi Apparatus](#)) to be sorted into each destination. Peroxisomes functioning in oxygen metabolism and fatty acid degradation ([Peroxisomes](#)) and lipid droplets specialized for lipid storage and metabolism ([Lipid Droplets](#)) are also discussed. Wauben ([Extracellular Vesicles](#)) discusses the most-recently discovered organelles, extracellular vesicles, which are released from cells and have diverse important physiological functions. While the above-mentioned organelles are ubiquitous in most cell types, there are some cell-type-specific organelles. Only plants and algae have chloroplasts for photosynthesis ([Plastids: The Anabolic Factories of Plant Cells](#)). Nerve cells in animals possess synaptic vesicles for neurotransmission, as described in the article [Synaptosomes and Synaptic Vesicles](#). Lastly, Fukuda ([Lysosome-Related Organelles](#)) discuss a group of organelles having very specialized functions, for example, pigmentation derived from lysosomes. These lysosome-related organelles exist in various highly differentiated cells.

Interorganellar Communication

The compartmental organization of the eukaryotic cell is essential for the development of multicellular organisms, for the organization of tissues and organs, and the coordination of physiological functions. The molecular processes which regulate the biogenesis of membrane compartments and the mechanisms by which information is shuttled back and forth between the different intracellular compartments represents fundamental processes in all eukaryotic cells. The pioneering work by Palade and colleagues, which integrated EM technologies with biochemical approaches, laid the foundation for understanding organelle dynamics and interorganellar communication. Subsequent work over the past 3–4 decades has revealed many of the molecular mechanisms which regulate these processes.

This section focuses on the molecular mechanisms underlying membrane transport pathways. ER export and ER stress responses are now well-understood and discussed in the articles [ER–Golgi Transport](#) and [Endoplasmic Reticulum Stress in Disease](#). Golgi organization and transport is a complex field that has invoked a variety of ingenious approaches in an attempt to define the underlying mechanisms of intracellular transport, as discussed in the article [Intra-Golgi Transport](#). The Golgi is also the site for the glycosylation, and the biosynthesis and role of N-linked glycans and O-glycans in cell biology and development that are discussed in the articles [N-Linked Glycans \(N-Glycans\)](#) and [Extracellular O-Glycans](#), respectively. An emerging field arises from the appreciation that signaling controls transport along the constitutive secretion pathway ([Regulation of the Secretory Pathway](#)). Post-Golgi transport involves

multiple pathways from the *trans*-Golgi network to the cell surface and constitutive and regulated post-Golgi transport are discussed in the articles [Post-Golgi Transport – Cargo, Carriers, and Pathways](#) and [Regulated versus Constitutive Secretion – A Major Form of Intercellular Communication](#). Endocytosis is also an important element of interorganellar transport, and this section discusses both the clathrin-mediated and non-clathrin-mediated pathways in the articles [Clathrin and Clathrin-Dependent Endocytosis](#) and [Clathrin Independent Endocytosis](#). Transport along the endosomal–lysosomal pathway is covered in the article [Endosome to Lysosome Transport](#), and pathways that carry cargo along the retrograde transport route from the endosomes to the Golgi are discussed in the article [Retrograde Transport](#). Machinery components of vesicle formation and vesicle fusion are essential for the regulation of these transport pathways, and in particular include small G proteins ([Rabs of the Endosomal Recycling Pathway; Rabs and Other G Proteins](#)), phosphoinositides ([Interorganellar Communication: Role of Phosphoinositides in Membrane Traffic](#)), Bar domain proteins ([BAR Domains and BAR Domain Superfamily Proteins](#)), SNAREs ([SNAREs: Membrane Fusion and Beyond](#)), ESCRTs ([ESCRTing around the Cell](#)), exocyst and tethering factors ([Vesicle Tethers](#)) and components of the vesicle coats that interact with cargo, such as adaptor complexes ([Adaptor Proteins: Inter-Organellar Traffic Controllers](#)) and retromer ([The Retromer Complex](#)). And finally also included are pathways of cell secretion that are independent of the pathway involving the ER and the Golgi, referred to as unconventional protein secretion ([Unconventional Protein Secretion: Fibroblast Growth Factor 2 and Interleukin-1 \$\beta\$ as Examples](#)).

Cytoskeleton and Motors

The ability of cells to regulate their shape, organize their components, move, and divide depends on the networks of filaments collectively called the cytoskeleton. In contrast to the human skeleton, which remodels slowly, most cytoskeletal filaments are dynamic, because they are composed of polymers of small building blocks that can rapidly assemble and disassemble, depending on the cellular needs. Growth and depolymerization of cytoskeletal filaments can generate forces that can drive cell protrusion and promote chromosome separation during cell division. Moreover, some cytoskeletal filaments can serve as rails for the movement of motor proteins, which use the energy released by ATP hydrolysis to perform mechanical work. The activity of such motors is responsible for the locomotion of single cells, cell contraction and intracellular transport of membrane organelles, RNA, and protein complexes.

This section describes the composition, structure, and dynamics of the major eukaryotic cytoskeletal filaments: actin ([Actin Assembly Dynamics and Its Regulation in Motile and Morphogenetic Processes](#)), microtubules ([Microtubules and Microtubule-Associated Proteins \(MAPs\)](#)), intermediate filaments ([Intermediate Filaments](#)), and septins ([Septins: Cytoskeletal Filaments with Structural and Regulatory Functions](#)). A separate article is dedicated to the structurally and functionally diverse cytoskeletal networks present in bacteria and archaea ([Bacterial and Archaeal Cytoskeletons](#)). Subsequent articles discuss the molecular mechanisms, motile properties,

and functions of the major cytoskeletal motor families. These include the actin-based motors, myosins ([Myosins](#)), and the microtubule-based motors, kinesins ([Kinesin Superfamily Proteins \(KIFs\) as a Fundamental Component of Life: Intracellular Transport and Beyond](#)) and dyneins ([Dyneins](#)).

An important property of the cytoskeletal components is their ability to form complex structures, which perform elaborate cellular functions. The article [Centrioles and the Centrosome](#) discusses centrioles and centrosomes, which are responsible for microtubule organization. The article [Cilia and Flagella](#) describes microtubule-based protrusions, cilia and flagella, which are required for motility or sensory and signaling functions. The intricate cytoskeletal machine that drives chromosome separation during cell division, the mitotic spindle, is discussed in article [The Mitotic Spindle](#). The motile and contractile properties of cells and whole organisms strongly depend on actin-based structures, such as filopodia and lamellipodia ([Filopodia and Lamellipodia](#)) or muscle fibers ([Skeletal Muscle](#)). Formation of complex cytoskeletal assemblies, which is strongly regulated by signaling factors, such as Rho GTPases ([Rho GTPases](#)), enables cells to adhere to the extracellular matrix ([The Extracellular Matrix; Cell Adhesion to the Extracellular Matrix](#)) or to each other ([Cell–Cell Adhesion and the Cytoskeleton](#)), polarize ([Cell Polarity](#)), and migrate ([Cell Migration](#)).

Intracellular Infectiology

The interaction between viral, bacterial, and protozoan pathogens and eukaryotic cells has been of interest to biologists and physicians for over two centuries, since Metchnikoff noted the internalization of bacteria by wandering mobile cells. With the advent of modern cell biology and the emergence of imaging and molecular biology technologies in the past three decades, the field of host defense against pathogens and its failure – resulting in intracellular infection – has advanced at a very rapid pace. Understanding how pathogens access the portals of entry normally reserved for nutrition and defense has intrigued a generation of cell biologists not only from the point of view of expanding our knowledge of normal cell behavior but also of getting a better handle on the molecular mechanisms that invasive organisms use to access intracellular niches where they proliferate. Moreover, understanding the molecular mechanisms of intracellular infection opens up a window of opportunity to develop therapeutics. This section of the Encyclopedia initiates a journey through the various pathways and processes that cells use to kill pathogens by laying out the mechanisms of phagocytosis ([Phagocytosis](#)), including a description of the various traffic events that bring the internalized microbes into compartments designed to kill and dismember the invader. Many small particles (and fluid) access the cell by macropinocytosis, a process first described by Lewis almost century ago. In article [Macropinocytosis](#) Swanson and Yoshida describe the role of macropinocytosis in cell growth, antigen processing, and infection by virus and

bacteria. Intracellular killing is mediated by reactive oxygen species carried out by complex oxidases, assisted by powerful cationic antimicrobial peptides. Allen ([Microbicidal Mechanisms](#)) lays out the basis for intracellular killing as an important component of host defense. Pathogenic bacteria and protozoa have evolved mechanisms to resist killing by host cells; the molecular details of these mechanisms are truly intriguing. Using examples from common pathogens such as *Brucella*, *Chlamydia*, *Legionella*, *Listeria*, *Salmonella*, and *Shigella*, Isberg and colleagues ([Bacterial Subversion of Phagocytic Killing](#)) lay out the pathways that intracellular pathogens use to evade detection and killing, thereby permitting residence in intracellular niches where they proliferate. Ferrari and Sansonetti ([Cellular Invasion by Bacterial Pathogens](#)) extend this analysis, focusing on the molecular mechanisms of pathogen uptake by nonphagocytic cells and how certain pathogens survive by subverting cellular functions. Lastly, Rigoni and Montecucco ([Bacterial Protein Toxins as Tools in Cell Biology and Physiology](#)) discuss potent toxins that increase the possibility of bacterial survival in the face of an effective microbicidal immune system, and how these toxins have become useful reagents in cell biology research. In addition to pathological interactions, the interaction between bacteria and host cells may operate in a saprophytic relationship. Together with the advent of NGS, this concept has opened up a new field called the microbiome ([The Gut Microbiome](#)).

A second large group of pathogens are the viruses, which need to infect host cells to replicate themselves. Helenius ([Cell Biology of Virus Infection](#)) describes the process by which viruses enter cells to exploit the cell's transport and synthetic pathways. Extending this analysis, Wileman and colleagues ([Virus Factories and Mini-Organelles Generated for Virus Replication](#)) describe how various viruses develop factories for efficient intracellular replication. One virus- HIV- has received intense scrutiny at the molecular, cellular, and biomedical/epidemiological levels leading to an impressive while ever improving understanding of its life cycle. Giese, Pelchen-Matthews and Marsh ([HIV – The Cell Biology of Virus Infection and Replication](#)) provide a article outlining in detail the Cell Biology of Virus Infection and replication.

Over the last two decades another type of disease transmission has emerged, following the discovery of prions. Legname and Pischke ([Prions](#)) discuss the cell biology and transmission of scrapie and other prion diseases. Lastly, model organisms being used to understand the relationship between pathogen and host are discussed. Sun and colleagues ([Cellular Responses to Infections in *Caenorhabditis elegans*](#)) describe the cellular responses to infection, using *Caenorhabditis elegans* as a model organism.

Introduction

One of the emerging structural methods in modern cell biology is single-particle electron cryo-microscopy (cryoEM). Recent advances in single-particle cryoEM have enabled near-atomic ($\sim 3\text{--}4\text{ \AA}$) resolution for structures of macromolecular complexes ranging from large icosahedral virus particles and molecular machines to moderate-sized enzymes and membrane proteins (e.g., Zhang *et al.*, 2010b; Bai *et al.*, 2013; Bartesaghi *et al.*, 2014; Liao *et al.*, 2013; Lu *et al.*, 2014). What makes this method unique is that the macromolecular complexes can be observed under nearly physiological or biochemical conditions, without artifacts possibly generated from either staining or crystallization.

Monodisperse particles of macromolecular complexes are frozen in vitreous ice. Thousands to hundreds of thousands of two-dimensional (2D) images of these particles are recorded in an electron microscope with a cryo-specimen stage. These particle images are computationally processed to generate a three-dimensional (3D) map and (with sufficient resolution) an atomic model of the macromolecular complex, which are deposited to the EMDData Bank and Protein Data Bank for public access (see Section Relevant Website).

Since numerous reviews have been written to describe the detailed protocols for each of these steps (Chang *et al.*, 2012; Baker *et al.*, 2010), we will not repeat them here. However, we will describe some cautionary notes about the hurdles often encountered in each of the steps. Then we will present some examples that illustrate the types of structural information that can be derived from cryoEM structures.

CryoEM Sample Consideration

For single-particle cryoEM, samples are diluted to a concentration of $\sim 0.1\text{--}1\text{ mg ml}^{-1}$ in a suitable buffer, in order to

ensure the particles are well separated from each other. Certain commonly used buffer constituents like glycerol and sucrose have an adverse effect on the image contrast and should be avoided or diluted out during the cryo-specimen preparation step. The molecular mass of the macromolecular complex can be as large as tens of MDa. Due to the weak contrast in the cryoEM images, there is generally a lower limit to the size of the macromolecules that can be recognized in images (Henderson, 1995). Recently, a cryoEM structure of a 170 kDa membrane protein was solved to 4.5 Å resolution (Lu *et al.*, 2014). For DNA/RNA, much smaller sizes can be imaged due to the stronger electron scattering power of the phosphate backbone. A low-resolution structure of a 50 kDa folding intermediate of a ribozyme domain has been reported using single-particle cryoEM (Baird *et al.*, 2010).

Compositional and conformational heterogeneity is commonly seen in biologically active complexes. Compositional heterogeneity occurs when the imaged particle is composed of multiple loosely connected components, or a ligand is weakly bound to its target. One successful biochemical method to minimize such sample heterogeneity is to mildly cross-link the subunits in the complex, then purify the cross-linked complex using ultracentrifugation or gel filtration techniques (Murakami *et al.*, 2013; Shukla *et al.*, 2014). Conformational heterogeneity could be large or small, continuous or discrete, but is commonly seen in single-particle cryoEM, since different parts of the macromolecules can have different dynamic motions in their biologically active states. For certain macromolecules, small ligands bound in the active site or other binding pocket may stabilize their structures and thus minimize the conformational heterogeneity. For example, non-hydrolyzable ATP analogues are commonly used to trap molecular chaperones in one of their ATP-dependent transition states, making the chaperones more uniform and sometimes more rigid in conformation (Zhang *et al.*, 2010a). We

should point out that cryoEM can deal with samples with compositional and/or conformational heterogeneity by various data sorting algorithms during image processing (Scheres *et al.*, 2007; Elad *et al.*, 2008; Penczek *et al.*, 2011; Elmlund and Elmlund, 2012; Chen *et al.*, 2006).

Frozen, Hydrated Specimen Preparation

An electron microscopy grid is equivalent to the glass slide in light microscopy. It provides a surface to support the specimen in the electron microscope. The standard grid is a thin copper or other metallic foil mesh with a diameter of 3.05 mm; it is covered by thin carbon film with periodically arranged holes (1–2 μm). Ideally, the specimens are suspended in these holes. In some cases, the particles may stick to the support net of the grid or do not stick to the grid at all. A thin carbon support film across the holes often works to recruit the particles but suffers from introducing a higher background to the images. Recently, innovative methods have been put forward to help anchor the particles on a cryoEM grid using graphene or specific affinity surface labeled molecules (Russo and Passmore, 2014; Kelly *et al.*, 2010).

Several semi-robotic devices (FEI Inc., Gatan Inc., Leica Inc.) have been developed to aid in preparing the frozen, hydrated specimen on a cryoEM grid. Many of these devices allow the users to control vitrification parameters such as the duration and force of the blotting, the temperature and humidity of the environment, etc. Standardization of these parameters improves the sample quality and the reproducibility of the experiment. To obtain single-particle cryoEM images of the specimen with good contrast, the ice must be as thin as possible while still fully embedding the specimen particles, keeping them in the frozen, hydrated state. Contamination of the sample by crystalline ice can occur when the processes of freezing or transferring the sample are not performed well. For example, the liquid ethane may not have been cooled down enough by the liquid nitrogen, or the grid may have been exposed to warm or humid air during the multiple grid transfers from the freezing apparatus to the microscope column. This type of contamination can be minimized by proper handlings of the frozen grids in various transfer steps and always keeping cryoEM room at low humidity.

An often-encountered frustration in cryoEM specimen preparation is referred to as the ‘preferred orientation’ of the particles embedded in ice. To obtain a 3D density map of the macromolecular complexes using cryoEM, 2D images of the particle must cover all orientations with respect to the incident electrons. Some particles have a preference to lie in certain orientations, generating insufficient data sampling for a 3D reconstruction. Such preferred particle orientation may be due to a surface-exposed patch of hydrophobic residues, for instance, which tends to be attracted to the air/ice interface on the grid. In this case, a small amount of mild detergent (e.g., 0.05% octyl glucoside) added to the buffer, may induce the particles to adopt a more random orientation on the grid before freezing (Zhang *et al.*, 2010a). One may also genetically mutate or remove the exposed hydrophobic residues, if the overall structure of the molecule is not changed (Zhang *et al.*, 2010a).

CryoEM Image Acquisition

Special care must be taken when imaging with electrons, as radiation damage will occur if the ice-embedded specimen is overexposed, leading to a loss of structural information. In order to minimize the radiation damage to the specimen, the total electron exposure applied to the specimen must be limited. About 15–25 electrons per $\text{\AA}^2$ are regarded as a safe specimen exposure for subnanometer resolution structure determination (Bammes *et al.*, 2010). The data collection can be automated (Nakamura *et al.*, 2010; Zhang *et al.*, 2003, 2009; Lei and Frank, 2005; Carragher *et al.*, 2000).

A recent exciting development in single-particle cryoEM is the availability of new generation direct electron detection cameras (Bammes *et al.*, 2012; Bai *et al.*, 2013; Li *et al.*, 2013). Compared with the traditional recording media such as charge coupled device (CCD) cameras, direct electron detection cameras omit the scintillator and thus avoid the random scattering of electrons when they travel through the scintillator, thereby minimizing the noise and enhancing the quantum detection efficiency. With their ultrafast refreshing rate, multiple frames of images from the same specimen area can be recorded and aligned computationally to correct for any image blurring due to the electron beam-induced movement or mechanical stage instability during image acquisition. Figure 1 shows an image of ice-embedded single particles of ribosomes before and after multiple frames of an image have been drift-corrected and averaged. It is clear that the power spectrum of the aligned average has more isotropic and higher resolution contents than the nonaligned average.

While the new digital cameras achieve cryoEM images with significantly better quality, the amount of raw digital data has dramatically increased from tens of megabytes for each micrograph to several gigabytes for a stack of frames. One stack of frames is taken from the same specimen location on the grid while fractionating the total electron exposure into each of the frames within the stack. Thus, it is feasible to acquire 0.5–1.0 TB of single-particle image data in a few hours of data collection. This poses a major challenge for data transfer between the microscopes and the data-processing computers and for the data archiving in the database; a much faster speed of the network connections and larger storage space are required.

CryoEM Image Processing

Image processing consumes a major block of time in the cryoEM workflow to convert 2D images into a 3D density map. Image processing consists of multiple steps, including image quality assessment, particle picking, determination and correction of image defocus effects, estimation of particle orientation parameters, map validation, model building and validation. There are multiple challenges in the workflow.

The first is to align the raw 2D particle images against the projection images of a 3D template, which are iteratively updated. There are many ways to generate an initial template. One way is to identify three orthogonal views of 2D images to generate a rough model (e.g., a barrel for a mammalian chaperonin (Cong *et al.*, 2011)). Another way is merely to generate a featureless model with an approximate size and shape (e.g.,

Figure 1 The cryoEM micrographs of the ribosome particles and their power spectra before (left) and after (right) drift correction. The ribosomes are directly frozen in the vitreous ice on a C-flatTM grid without continuous carbon support. The images were collected at a nominal magnification of $19\,000\times$ on a Gatan K2 Summit electron counting direct detection camera with an FEI Tecnai TF20 electron microscope.

spherical shell for a virus particle (Liu *et al.*, 2007)). Experimentally, one can also generate an initial model using random conical tilt or orthogonal tilt imaging (Radermacher *et al.*, 1987; Leschziner and Nogales, 2006). In these later methods, the same particles are imaged as pairs from two angles respectively. These are usually $0^\circ/55^\circ$ tilt pairs for random conical tilt and $-45^\circ/45^\circ$ tilt pairs for the orthogonal tilt methods. The resultant map can then be used as an initial template which is refined into a higher resolution map using the low-dose, untilted images. Particle orientation determination is an iterative process that gradually improves the accuracy and resolution of the map (Ludtke *et al.*, 1999; Tang *et al.*, 2007; Shaikh *et al.*, 2008; van Heel *et al.*, 1996; Grigorieff, 2007).

Another commonly encountered challenge in single-particle cryoEM image processing is the existence of multiple particle conformations in the population of particle images. With such data, one has to first separate the different conformations in the specimen, and ultimately reconstruct a density map from each of the data subsets (Chen *et al.*, 2006; Scheres *et al.*, 2007).

There are multiple image processing software packages which will carry out some or all of these steps. There is a current trend to hybridize different software to take advantage of the strengths of the algorithms in different software packages. In some cases, one may apply different image

reconstruction procedures to help validate the maps of specimens (Murray *et al.*, 2013). Other approaches have recently been proposed to build or refine 3D models directly against 2D cryoEM images (Zhang *et al.*, 2012; Velazquez-Muriel *et al.*, 2012) in order to address the problems due to structural heterogeneity or preferred orientations of the sample on the electron microscope grid.

Since cryoEM reconstruction can be completed at various resolutions ($40\text{--}3\text{ Å}$), the validation criteria of the map vary. One approach to validate the final refined map is called tilt-pair validation technique (Rosenthal and Henderson, 2003). A few particle image pairs of the same specimen are collected at 0° and $\sim 10^\circ$ tilt. The orientation of these image pairs can be determined by using the final refined map as an alignment reference. If the final map is correct, the determined orientations between the same particles in each tilt-pair image should differ by the 10° that was imposed experimentally.

Resolution of CryoEM Density Maps

For a long time, there was no uniform practice in reporting the resolution of a cryoEM map. Recently, a gold standard for this issue has emerged, and has been adopted in many publications since 2013 (Scheres and Chen, 2012; Henderson *et al.*,

2012). This resolution estimation is to split the raw particle images randomly into two groups and processing each of the groups independently. Fourier transformations of the two maps are then computed. These transformations are independently averaged in spherical shells, and then the two sets of shells are correlated, in the Fourier space, a procedure known as the Fourier Shell Correlation (FSC). The FSC shows how well the two maps agree with each other as a function of resolution. It has been shown analytically that the resolution at which the FSC value equals 0.143 is appropriate to report the resolution of the final map generated by the whole particle data set. A common fault in the map determination is over-refining the data so that the map resolution is over-estimated (DiMaio *et al.*, 2013). To avoid such occurrence, it has been suggested to run a test in which the image data has its phases randomized beyond 75% of the claimed resolution (Chen *et al.*, 2013b). The resolution of the maps computed from such data should fall off sharply at the resolution where the data are randomized, indicating no over-refinement (Wang *et al.*, 2014). The true resolution can be estimated accordingly.

Nevertheless, a single value at a certain threshold of the FSC gives only an overall quality of the density map. The resolution of a reconstructed map may not be uniform throughout the entire macromolecular complex. Therefore, efforts have been made to estimate the local resolution variations in a cryoEM density map (Kucukelbir *et al.*, 2014) or to compute the 3D variance map using a statistical bootstrapping approach (Penczek *et al.*, 2006; Chen *et al.*, 2008).

Needless to say, the ultimate judgment of the map resolution is the details of the structure features in the final density map: alpha-helices appear at ~ 10 Å resolution and become clearer beyond 7 Å resolution; the pitch of the alpha-helices

becomes evident at better than 5.5 Å resolution; the separation of beta-strands and the connectivity of the protein chain (in mostly alpha helical proteins) start to be resolved at 4.5 Å (Baker *et al.*, 2013). The resolvability of C-alpha backbone and many sidechains would become better as the map extends beyond 4 Å resolution.

CryoEM Model Building and Model Validation

Once a cryoEM density map is obtained, one can start to interpret its details by building the atomic coordinates of the protein or nucleic acid into the map. If a homologous structure is known for a component in a complex, it can be docked into the density by rigid body or flexible fitting. Several flexible model-fitting techniques based on different physics principles have been developed (Schröder *et al.*, 2007; Topf *et al.*, 2008; DiMaio *et al.*, 2009; Trabuco *et al.*, 2008; Hinsen *et al.*, 2005; Tama *et al.*, 2004). For cryoEM maps determined at sub-nanometer (< 10 Å) resolution, when many secondary structure elements are visible, the docking of molecular components becomes more reliable because the alpha-helices and beta-sheets serve as anchor points to guide the modeling process. At even higher resolutions, when many protein side chains are visible, one can build a *de novo* model restrained by the density, followed by model optimization using and modifying tools already existing for crystallography (Baker *et al.*, 2010).

Interpretation of low-resolution (lower than ~ 10 Å) density maps is nontrivial, especially when the map is a complex of multiple components. Methods like cross-linking mass spectrometry have been developed to facilitate the

Figure 2 CryoEM map and model of the wild-type Mm-Cpn chaperonin in the top view (a) and side view (b). The pairwise C-alpha deviations between the cryoEM model and the crystal structure are less than 4.3 Å (c). The blue color indicates lower pairwise C-alpha deviations and the red color indicates higher pairwise C-alpha deviations.

Figure 3 Gallery of a few cryoEM structures solved to 3–4 Å resolutions. PYD inflammasome filament (left, EMD-5830), human gamma secretase (top middle, EMD-2677), TRPV1 ion channel (bottom middle, EMD-5778), Brome Mosaic Virus (top right, EMD-6000), and archaeal 70S ribosome (bottom right, EMD-2277). The scale bars denote 50 Å.

annotation of different components in a cryoEM density map by providing their relative spatial information. Combining cross-linking mass spectrometry with cryoEM is also useful for deriving a model (Leitner *et al.*, 2012).

Model validation is an important step to assure the model is not overfitted with the density data. There are many ways to assure the model is properly optimized. A necessary check is to measure the FSC between the model and the experimental map. The resolution should be close to that of the claimed resolution derived from two independent maps. Another way is to compare independent models derived from each of the half data sets. An FSC of a model derived from one map can be quantitatively computed against the other map (DiMaio *et al.*, 2013). In addition, the RMS deviation of the two models can be quantified to estimate which regions of the model are more robustly determined than the others.

High-Resolution CryoEM Structures

In 2008, four cryoEM structures were reported to show backbone connectivity in individual components of a chaperonins and icosahedral viruses (Ludtke *et al.*, 2008; Jiang *et al.*, 2008; Yu *et al.*, 2008; Zhang *et al.*, 2008). A subsequent *de novo* cryoEM structure was determined for Mm-Cpn, an archeal chaperonin with two back-to-back rings of 16 homoprotomers (Zhang *et al.*, 2010a). Though the exact resolution of this map is lower than the published claim by today's gold standard criterion (DiMaio *et al.*, 2013), the reported backbone of Mm-Cpn was later confirmed to be correct by a subsequent X-ray structure (Pereira *et al.*, 2010), and the pairwise

C-alpha deviation is rather small between the two structures, with the higher deviations mostly in the loop regions of the subunits (Figure 2).

In the last 2 years, there have been an increasing number of atomic resolution maps (<4 Å) generated by cryoEM for icosahedral viruses, ribosomes, membrane proteins, enzymes, and helical filaments (Figure 3 for selected examples). These structures were made possible primarily due to the revolutionary development of the direct-electron detectors. All of these structures give rise to *de novo* models with clear backbone topology and sidechain densities (Figure 4).

Identifying Different Populations Within a Heterogeneous Sample

GroEL-ES is a molecular chaperone complex that helps other proteins fold correctly in the cell. Each GroEL complex consists of two back-to-back rings, each composed of seven subunits. GroES is a heptameric co-chaperonin that caps the GroEL after the substrate is encapsulated, concurrently with the ATP hydrolysis. Substrate binding and folding is a complex biochemical process. A biochemical mixture of GroEL, GroES, substrate, and ATP is bound to generate multiple reaction products (e.g., GroEL alone, GroEL with GroES capped, GroEL with the substrate, GroEL plus GroES with the substrate in the folding chamber, and the GroES can bind to either one ring or both rings). Such a heterogeneous sample presents challenges in sorting out the structures of the reaction products. Biochemists can carefully control the experimental conditions or use GroEL mutants to reduce the number of different

Figure 4 CryoEM maps and models of the Brome Mosaic Virus showing the sidechain densities. Reproduced from Wang, Z., Hryc, C.F., Bammes, B., *et al.*, 2014. An atomic model of brome mosaic virus using direct electron detection and real-space optimization. *Nature Communications* 5, 4808.

Figure 5 Front view (left) and side view (right) of the cryoEM density map of GroEL/ES complex with the substrate protein RuBisCO in the folding chamber reconstructed without any symmetry enforcement (EMD-2326). Each of the GroEL subunits is colored differently. GroES is colored in purple while the yellow color is the RuBisCO substrate directly interacting with the stem loops of the GroEL. The scale bar denotes 50 Å. Reproduced from Chen, D.H., Madan, D., Weaver, J., *et al.*, 2013a. Visualizing GroEL/ES in the act of encapsulating a folding protein. *Cell* 153, 1354–1365.

Figure 6 CryoEM maps and models of the lidless Mm-Cpn in the top views (top row), side views (center row), and the model of a single subunit (bottom row). From left to right, the Mm-Cpn is its ATP-free, ATP-bound and ATP-hydrolysis states, respectively. Domains in the Mm-Cpn subunit rotate around different hinges (labeled by the gray triangles) in these different ATP states to close the folding chamber.

conformations within the system (Chen *et al.*, 2013a). Even with many different biochemical approaches to control the chaperone's state there may still be a lot of distinct conformations within the sample solution. Single-particle cryoEM combined with image processing has been used to successfully separate the different conformations and visualize a native substrate RuBisCO inside the GroEL/GroES complex (Chen *et al.*, 2013a). The structure shows the breakdown of the seven- and twofold symmetry of GroEL-ES and the RuBisCO binding the equatorial domains of the GroEL (Figure 5).

Delineating the Conformational Changes of a Molecular Machine

Mm-Cpn is a different chaperonin that can fold proteins without the need of a co-chaperonin (Zhang *et al.*, 2010a). It also has two back-to-back rings but with eight identical subunits per ring. It opens and closes during its ATP-driven cycle. Using single-particle cryoEM, structures were determined for Mm-Cpn under the ATP-free, ATP-bound, and ATP-hydrolysis conditions. Figure 6 shows the cryoEM density maps and models of the Mm-Cpn under different ATP states. The Mm-Cpn slightly closes its folding chamber after ATP-binding and completely closes it upon ATP-hydrolysis (Zhang *et al.*, 2011).

These conformational changes also alter intra- and interring contacts. This mechanism of structural changes in response to ATP is entirely different from those found in GroEL and GroES complex.

Conclusion

The ability of relatively rapid determination of 3D density maps of proteins and protein complexes has led single-particle cryoEM to become an integral part of modern cell biology. It can be anticipated that resolution of cryoEM maps will continue to improve and more effective methodologies to handle particle heterogeneity will be emerged. Already it is supplanting established structural techniques for macromolecules that are not readily analyzed by NMR or X-ray crystallographic methods, such as the human gamma secretase (Lu *et al.*, 2014). It is certain that biochemical protocols to prepare suitable specimens for cryoEM will continue to be developed. Furthermore, the ability to visualize proteins in various conformations, as illustrated with GroEL and Mm-Cpn, enables researchers to elucidate the molecular mechanisms of cellular processes. The ability to model protein in multiple conformations facilitates the ultimate purposes of structural biology: determining its mechanisms of activities through visualizing

its structural intermediates and eventually identifying drug targets.

The recent technological advances in instrumentation, combined with new algorithms for image processing, have enabled single-particle cryoEM to yield reliable high-resolution maps and molecular models of large molecular machines, in which the protein backbone or even amino acid side chains can be identified and modeled. As a result, cryoEM will aid in the understanding of fundamental cellular processes. Structures established by cryoEM can foment drug discovery and lead to a greater comprehension of molecular interactions in biology.

Introduction

Long before the idea of scanning specimens with a small spot of light produced confocal light microscopy, the idea of using a small spot of electrons to scan surfaces had been around as long as electron microscopy (EM) itself. A surface demarcates the boundary of a solid and is the site of interaction with the surrounding environment, from a living cell to a ball bearing. In the mechanical world, adhesion, friction, wear, and corrosion are all dependent on surface properties. Living material, even those which have a solid nature such as bone, have surface properties infinitely more dynamic than the humble ball bearing. In a unicellular tissue such as blood, the white cells which are responsible for our immune defenses rely on surface molecules which are constantly recycled and redistributed to recognize and respond to infective agents such as bacteria and viruses. In multicellular tissues, information is incessantly passed between neighboring cells via their surfaces, and the progression of nerve impulses relies on electrical charge variation across the surface of neurons. Within the cell, most catalytic reactions are brought about by enzymes acting at the surface of membranes. All adhesion relies on surface properties, be it interactions between a tire and the road surface (enough friction to move the car or enough adhesion to prevent skidding?). Modifications of cell membranes such as formation of desmosomes in multicellular tissues provide remarkable mechanical strength and flexibility at the surfaces of both skin and internal organs. Although microscopy, in general, and scanning electron microscopy (SEM), in particular, are not the only ways of characterizing surfaces, they are the cornerstone of understanding their structure and properties.

Scanning Electron Microscopy 'Versus' Transmission Electron Microscopy

Rather than passing a 'flood' beam of electrons through a thin sliver of material as in transmission EM (TEM), SEMs move a small spot of electrons to and fro in a pattern of horizontal lines over the specimen surface (a raster). It is important to note that resolution in the SEM is not determined by the wavelength of electrons, as it is in the TEM, but by the diameter of the spot of electrons. It is this area (and the depth to which the beam penetrates) which generates the 'interaction volume' from which the signal is produced. As the beam diameter is reduced, so is the interaction volume, and resolution is increased. This constraint caused SEM to be considered 'low resolution' by TEM purists, and it took until the mid-1980s with the first commercial in-lens, field emission instrument from Hitachi, the S-900, for SEM to come close to the resolution of the TEM. However this type of instrument remained an expensive rarity, confined to only a few biology labs around the world and it is only relatively recently that

such instruments have become more widely available to cell biologists. Thus although SEM cannot claim the same massive strides forward in understanding of cell structure provided by Palade, Porter, Fawcett, and other TEM pioneers in the 1950s and 1960s, what it has done is to turn the 2D black line representation of membranes visualized in the TEM into a 3D surface representation of unimagined complexity (Figures 1(a) and 1(b)).

Construction of the SEM

From the top of the column to the specimen, there is little difference between a SEM and a TEM. Both have a source of electrons at the top of an evacuated column, and a set of condenser lenses to focus the electron beam onto the specimen. First-generation SEMs used the same source of electrons as TEMs, a 'V' shaped tungsten wire heated to around 1500 °C. Heating provides the energy required to remove electrons from the atoms in the tungsten, overcoming a barrier called the work function. If the amount of extracted electrons can be increased then a brighter, smaller spot can be used to scan the specimen, increasing resolution. The first improvement in electron sources was to use a crystal of Lanthanum hexaboride (LaB6), which has a lower work function than tungsten, increasing the available intensity tenfold. The next stage, which produced a further hundredfold improvement in intensity over LaB6, was to use a field emission gun (FEG). In field emission, electrons are extracted from an ultrafine needlepoint of tungsten by the application of a powerful electric field close to the tip. This overcomes the work function in a process called electron tunneling. This requires a vacuum of two orders of magnitude greater than conventional electron sources, requiring ion pumps. FEGs can be either 'cold' (room temperature), or heated. Cold FEGs are the most effective, but can become unstable as a single gas molecule can contaminate the tip, causing instability and a reduction in emission. A compromise with better stability and lower vacuum requirements, but resulting in slightly lower resolution, is thermal (or Schottky) field emission, in which the filament tip is both heated (which repels contaminants) as well as being subjected to an intense field. Most top-range SEMs (and many TEMs) have field emission sources, and are termed FEG-SEMs or FEG-TEMs (Figure 2).

Scanning the Specimen

Having generated an intense beam of electrons, the next stage in SEM is the point at which everything changes relative to TEM. Rather than illuminating the whole specimen in a 'flood beam,' electrons are concentrated into a small spot (demagnified) by two condenser lenses, and focused onto the surface

Figure 1 (a) Scanning EM visualization of a bone marrow stem cell (false colored). This typical visualization of a whole cell demonstrates both the surface and three-dimensional information available from this technique. (b) Higher magnification view of the surface of a human cell grown in tissue culture, showing the variation in surface projections termed microvilli, and the external membrane topography. The magnification ($15\,000\times$) shown is what the image was recorded at, and will vary according to the final size of the image, whereas the scale bar (667 nm) remains accurate.

Figure 2 A modern FEG-SEM instrument showing the column and the adjacent desk area, where the image is viewed on a monitor. The electron gun is mounted at the top of the column, evacuated by a series of ion pumps to produce a vacuum in which field emission of an electron beam is maintained.

of the specimen by the final lens directly above the specimen, sometimes (inappropriately) called the objective lens. The spot of electrons is moved across the specimen in a raster by a set of scanning coils which are usually contained within the final lens. These are four radially orientated electromagnets arranged so that their magnetic fields are perpendicular to the

axis of the beam. By varying the current, the beam can be controlled to scan across the chosen area of the specimen, building an image dot by dot and line by line. Magnification is determined by the chosen area of the scan as the final image is produced on a fixed size monitor. Thus if the scanned area is reduced by half, then the magnification will double. Most instruments will allow modest magnifications at the bottom end of their range (times 20 or so) up to 200 000 or even 3 million times in research grade microscopes. This massive range is useful with biological material, enabling selection of areas which have clean surfaces without physical damage, and to give confidence that the areas which are investigated are truly representative of the sample and to give an overall perspective. Image formation can be distorted by astigmatism, caused by lens imperfections when the beam becomes oval in cross-section rather than circular. This is corrected by the operator using a set of eight electromagnetic coils (stigmators). The final lens determines resolution by its formation of a minimum spot size (at best, 0.5–1 nm).

Beam – Specimen Interactions

If the scanned electron probe is ‘frozen’ at any one moment, then we can consider how the beam interacts with the specimen. Unlike TEM where the specimen has been suitably thinned to allow the beam to travel through, the bulk nature of specimens in SEM prevents this. The beam does penetrate the specimen surface to a depth that depends on the velocity of the electrons in the beam and the nature of the material in the sample but is generally around $1\,\mu\text{m}$, producing a volume of interaction shaped like a teardrop (Figure 3).

The collisions between the electrons from the beam and the atoms in the specimen surface lead to two types of interactions. Zero energy loss interactions result in elastic scattering

Figure 3 Interactions between the electron beam and the specimen surface. The beam penetrates the surface producing a 'teardrop' shaped interaction volume in which a variety of collisions take place.

where the primary beam electrons are simply deflected as they pass through the sample. In SEM, because the detectors are usually above the sample, only the most extremely elastically scattered electrons (by $\sim 180^\circ$), backscatter electrons, are of interest. If an electron transfers energy to the sample this is known as inelastic scattering. Inelastic scattering results in a change in velocity (and hence wavelength) of the electron, which in itself is more important for TEM, but the transfer of energy results in the production of secondary electrons, and various types of radiation, X-rays and cathodoluminescence (visible light), all of which can be used in the SEM to gain information about the sample.

Secondary electrons are formed as a result of inelastic interactions with atomic electron clouds in the specimen where substantial energy transfer results in the ejection of electrons from the sample atoms. Secondary electrons, which originate from the sample (not the high energy beam) have relatively low energies and are generally the most important signal produced for high-resolution surface imaging. Backscattered electrons, also important in biology, are the result of an elastic interaction with an atomic nucleus in the sample and are high-energy primary beam electrons that are scattered backwards, 'reflected,' due to attraction to the atomic nuclei in the specimen so that they reemerge from the sample surface with high energy.

Image Formation

Images are formed by modulating the brightness on a monitor (which is scanned in synchrony with the electron beam)

according to the interactions generated by the beam moving over the specimen. The secondary electron signal is collected by a detector which is positioned adjacent to the specimen in the chamber, surrounded by a wire grid kept at 200 V (in order to attract the secondary electrons) in front of a scintillator (kept at 10 000 V). Having passed through the grid, a secondary electron strikes the surface of the scintillator to produce a photon, which travels down a light pipe to a photomultiplier which in turn converts photons into an electrical signal. This signal determines the brightness of the spot on the monitor to create the image. Thus the more secondary electrons emitted from any one spot on the surface of the specimen, the greater the signal from the detector, and the brighter the area seen at that point in the image on the monitor.

Backscattered electrons also contribute to image formation, and can be imaged alone by either reducing the voltage on the grid in the detector (as backscattered electrons have sufficient energy to reach the scintillator regardless), or they can be collected more efficiently by a dedicated solid state detector, usually placed directly above the sample to ensure maximum collection. Backscattered electrons are useful, as they can be used to map the distribution of elements in the specimen because the number of backscattered electrons is proportional to the atomic number of the element which scattered them. This property therefore gives contrast dependent on the atomic number of the material. This is useful in biology because antibodies, which can be used to label specific proteins and other macromolecules, can be tagged with gold nanoparticles, which have a high atomic number and can easily be distinguished from the low atomic number atoms predominant in biological material. As they tend to arise from deeper within the surface of the specimen however, backscatter electrons are not as good as secondary electrons for resolving surface topography. Backscatter electrons can also undergo inelastic interactions as they emerge from the surface, producing type II secondary electrons which add to the noise in the secondary image. However, because they are much less affected by charge build up in nonconductive samples than secondary electrons, they may be preferred for imaging of some samples if enough electrons are backscattered to form an image on their own.

Another signal comes from 'Auger' electrons (after the person who discovered them), emitted a very short distance from the surface of the specimen, where they are mostly absorbed, but do allow chemical mapping of surfaces to a high resolution (with a dedicated detector). The X-ray emission (bremsstrahlung) from a scanned specimen can be used for energy dispersive elemental analysis similar to TEM. Finally, cathodoluminescence (the production of visible light) can also be detected and although rarely used in biology, is useful in imaging the internal structure of material science specimens such as semiconductors.

A Brief History of SEM

SEM was considered as a possibility by Ruska himself (the 'father' and Nobelist for TEM) in the very early development of EM, as methods for making thin specimens for TEM only emerged later. In 1935, Knoll invented a scanning instrument to study the targets of television camera tubes, to be followed by scanning instruments produced in 1938 and 1942 by von

Ardenne and Zworykin, respectively. Von Ardenne's instrument was destroyed in an air raid on Berlin in 1944. In the USA, the RCA corporation produced TEMs, and were working on scanning instruments. However, largely because of difficulties in the vacuum technology of the time, together with the success of surface imaging using replicas in TEM, they never brought a SEM to market. Consequently, we had to wait until 1965 for the first commercial instrument, produced by the Cambridge Instrument Company in the UK, as a result of research started in 1948 by Charles Oatley and his team. Six months later this was followed by an instrument produced by the Japanese Electron Optical Corporation (JEOL). From its earliest days, SEM has proved to be a source of images that everybody could relate to, regardless of microscopic experience or scientific background. From early images showing great detail of everyday objects and animals, for example, the edge of a scalpel or razor blade or the multiple eyes of a spider, the extra information provided by the high magnification was instantly apparent, grasping the attention of the general public in a way that TEM images did not. Today, images of bacteria, stem cells, and tumor cells are a regular sight in TV news, documentaries, newspapers and magazines, usually brightly colored. False or pseudo-coloring of SEM images is useful for highlighting specific features, as well as increasing the overall impact (albeit sometimes on the garish side).

Specimen Preparation for SEM

An ideal specimen for SEM is a coin: it is dry (no water content), has a hard surface, is made of heavy elements, and is an electrical conductor. These properties ensure that there is no problem with the vacuum in the specimen chamber, a good signal will be produced by the interaction of the electron beam at the surface, and that any electrical charge from the beam can run away to earth due to the conductive nature of the coin. Contrast this with biological tissue, which is ~70% water, which would evaporate and degrade the vacuum in the specimen chamber at the same time as distorting the specimen as it dries. The cell surface is soft, allowing the electron beam to penetrate deeper, masking surface detail and limiting resolution together with heat damage from the beam. On top of this, the light elemental composition of our specimens (made up of carbon, hydrogen, oxygen, and nitrogen) means there will be little useful signal to form images. Finally, because biological tissue is a poor conductor, electrons will build up within the specimen until they have sufficient energy to find a way to earth, resulting in a discharge which generates a burst of signal brightness (known as charging) which obliterates what image there might have been in the first place. All in all, not the most promising starting point for high-resolution imaging.

Critical Point Drying

These obstacles need to be circumvented to observe biological material. Firstly specimen water is removed. However, drying soft biological surfaces is tricky, as the surface tension of the receding liquid layer during drying will damage fine (and fragile) surface structures. Liquids, however, have a 'critical

point' where both vapor and liquid states coexist, allowing surface tension effects to be avoided if vapor is removed above this critical point. The critical point for water requires conditions that are not compatible with biological specimens, a pressure of ~200 atm and a temperature of 374 °C. The critical point for CO₂, however, is 31.1 °C, at a pressure of 100 atm, which is compatible. Samples must be fixed (in a similar way to TEM samples), which means introducing extensive chemical cross-linking between the molecules in the sample to prevent extraction and reorganization during the subsequent steps, followed by replacement of the water in the specimen by solvent (e.g., ethanol), which is in turn replaced by liquid CO₂ in a pressure vessel. As the temperature is raised in the pressure vessel, the critical point is reached, at which point the meniscus at the surface of the liquid CO₂ disappears as all the CO₂ is converted to vapor. This gaseous CO₂ is then gently vented, and the specimen is now dried, free from the distorting effects of surface tension.

Sputter Coating

The specimen has retained its fine structure, but still has a light elemental composition (C, H, O, N) which will only produce a poor signal. These limitations are overcome by the deposition of a very thin layer of metal over the surface. For surface replicas made for TEM, the metal is evaporated from a point source to produce a shadowing effect (see Heuser, 2011), but for SEM an even coating is required. This is achieved by a process called sputter coating, in which a target disc of the coating metal is bombarded under vacuum by ionized gas particles (usually argon) which strike the surface and remove atoms which are then deposited evenly over the surface of the specimen. Gold, or an alloy of gold and palladium, produces excellent secondary electron emission, as well as being permanent and noncorroding, allows long storage of samples for future reference. With the highest resolution instruments however, the actual grains of gold in the coating can be resolved – resulting in the imaging of the coating itself rather than the underlying surface of interest. In these situations chromium (Apkarian, 1994) or tungsten is used, which is deposited with a smaller grain size (although at a slightly reduced secondary electron emission). For studies involving elemental contrast (using backscattered electrons at low resolution) the specimen surface is made conductive by sputtering a thin layer of carbon, which appears transparent in the final image.

Labeling for SEM

As with TEM, small metal particles, such as colloidal gold, are used as markers to show specific binding sites on biological tissue (for instance by coupling the gold to an antibody). In SEM a gold label is visualized as a bright sphere (rather than the black dot seen in TEM), usually using a backscatter detector which produces a high contrast image due to the difference in the amount of backscattered electrons produced by the high atomic number of gold relative to the surrounding material. As gold labeling and gold coating would produce similar

backscatter signals, carbon coating is usually used to allow the colloidal gold signal to stand out. To retain the best surface imaging, chromium coating (atomic number 24) does allow visualization of gold colloid (atomic number 79). Also, as the backscattered electron signal from gold is particularly strong, the backscatter image can be collected simultaneously with the secondary electron signal, so that both can be merged in the computer to give the clearest labeling as well as optimal surface imaging.

Cryoscanning EM

An alternative way in which the soft, wet, and largely non-conductive nature of biological material can be made dry and hard is by freezing, which is best done as rapidly as possible, converting aqueous water to vitreous ice in milliseconds, and avoiding ice crystal damage/effects, as with Cryo TEM methods. For Cryo SEM the frozen specimen is mounted within the specimen chamber on a cold stage (cooled by liquid nitrogen) often with a facility to fracture the sample with a cold scalpel blade, and a sputter coater which allows the freshly fractured surface to be coated with metal whilst still in the microscope vacuum system. This approach allows SEM observation of material that has been neither chemically fixed nor dehydrated.

Environmental SEM

The preparative requirements for SEM would seem to be difficult to get round, but the ingenuity of instrument manufacturers should not be underestimated. The simplest solution, with respect to sample preparation, however, is to completely remove the requirement for a vacuum environment in the specimen chamber. Although an electron beam can only be generated in a vacuum, once the electrons have been accelerated, they will continue to travel in a directed manner, and can still interact with a specimen even if that specimen is at atmospheric pressure (i.e., no vacuum). The way that electrons can be used for imaging at 'high pressure' (up to 100% humidity) is to generate a vacuum gradient between the electron source and the specimen chamber. Although the electron beam will begin to scatter as soon as it encounters significant gaseous molecules on its journey down the column, there are still sufficient interactions with the specimen to generate secondary and backscattered electrons. Secondary electrons cannot be detected with standard detectors because of the presence of gas in the chamber. However the use of a positively charged detector results in acceleration of the secondary electrons toward the detector. These electrons do not reach the detector but collide with gas particles, displacing further electrons from the gas atoms, which themselves are accelerated toward the detector, undergoing more collisions and amplifying the signal, which eventually reaches the detector.

Environmental SEM therefore can be used to image non-conductive, uncoated, even 'wet' samples (Donald, 2003). Resolution in environmental microscopes suffers because of the nature of image formation in a 'wet' or gas-filled chamber, but this is offset by the ability to view wet specimens without

pretreatment. Future improvements in imaging quality may make this an attractive proposition for 'au natural' cellular imaging by SEM.

Serial Block Face Imaging

A major recent advance involving environmental SEMs, which takes advantage of the ability to suppress charging is serial block face imaging (Hughes *et al.*, 2014). A major limitation of thin section TEM is that it is essentially a 2D technique. Despite invaluable cross-sectional detail, translating this into the 3D context of a whole cell, tissue, or organism can be difficult and in the cases of serial section reconstruction and EM tomography, is very time consuming. Samples for thin section TEM are fixed, dehydrated with a solvent, in a similar way to SEM samples, but then instead of drying, they are infiltrated with a resin, which is then polymerized, to provide a hard support from which extremely thin sections can be cut and imaged. Such sections are fragile and display artifacts such as compression, altering the dimensions of biological material within, making reconstruction from a series of sections even more difficult. It was found, however, that TEM-like images could be obtained by imaging the cut face of the resin block (instead of the section obtained from it) with a backscatter detector in a SEM. Because the resin is nonconductive, the use of an environmental SEM is required to prevent electron charge build up in the specimen. In this technique an ultramicrotome is placed inside the SEM, so that sections can be trimmed off the block face and discarded, revealing a new face deeper in the sample, which is then imaged. This can be automated so that hundreds to thousands of block faces can be imaged progressively deeper into the specimen, effectively providing cross-sectional images from the whole volume of a cell or tissue. These can then be reconstructed into 3D structures using computer software.

Merging SEM and TEM

When a thin specimen is viewed in a SEM, the electron beam will pass through it. If the detector is placed underneath (rather than above as usual) an image can be gathered that is similar to that of a TEM. From the early years of SEMs, this was well known, but rarely used, as the resolution would be relatively poor. However, as the resolution and quality of imaging in SEMs improved, certain advantages to this type of imaging came into consideration. In a TEM, the projector lenses which form the image below the specimen can suffer from blurring due to inelastically scattered electrons causing chromatic aberration. This does not occur in scanning instruments as there are no lenses below the specimen. Also, images can be collected in the SEM with digital detectors of almost unlimited pixel numbers (an enormous 32 K by 32 K in the Zeiss Atlas system). Finally, when the magnification is changed in the SEM there is no image rotation as there is in the transmission microscope. All these factors have been utilized in biological samples to produce impressive results in tomographical (3D) reconstructions at the cellular level. However, in terms of absolute (atomic) levels of resolution, the TEM is still the

instrument of choice, although many TEMs will also incorporate a scanned beam illumination to take advantage of this mode of imaging, termed STEM (Scanning Transmission EM).

Exposing Subsurface Detail

Having collected surface details by SEM, the possibility to then strip back this layer and expose underlying structures was a thought that occurred to most microscopists. Simple approaches, such as the use of adhesive tape (applied after fixation, gentle detergent extraction, and refixation followed by dehydration and critical point drying), at which point the cell is in a friable condition, produce an effect rather like taking the pastry off a pie, and exposing various levels below (Figure 4).

Although electron beam lacks the power to remove any material in the microscope, if electrons are substituted with something of heavier mass, and enough energy provided, then surface material can be stripped away little by little (termed 'milling'). This is achieved by a technique which uses a beam of focused ions generated from a source in which a tungsten filament coated with gallium is heated under vacuum. The molten gallium flows to the tip of the tungsten needle where gallium atoms are subjected to an electric field which produces ionization and field emission of gallium atoms. An atom of gallium, compared to an electron, is like a cannonball compared to an air rifle pellet. This beam bombards the specimen

surface removing atoms and also producing secondary electrons, often sufficient to produce an image. The amount of material removed can be controlled by varying the beam current. At low currents, little is removed, but the high density of signal allows high-resolution imaging. At high beam currents, large amounts can be removed allowing precision milling of the surface micron by micron. This technique is mainly used in semiconductor production and research, using 'dual beam' instruments (FIB-SEMs) which combine SEM imaging with a focused ion beam (FIB) for micromachining. Specimens are imaged with secondary electrons, then 'stripped back' using the ion beam, and imaged again. This can be repeated over and over, often under remote control, until a series of images of successive 'slices' have been recorded (rather like photographing the Sunday joint after each slice has been cut). These images can then be reconstructed in the computer to form a 3D map. The ion beam itself can be used to produce images, which may lack the ultimate resolution of electrons, but can be extremely useful as they show better elemental contrast of metallic grains in alloys and in mechanical failure and corrosion. As well as material science specimens, blocks of fixed and resin-embedded biological tissues and also frozen biological material can be milled to reveal fresh surfaces (Kizilyaprak *et al.*, 2014). Muscle tissue has been reduced by milling to a thin section for TEM, with promising results. The data obtained can be considered as similar to serial block face imaging, although the process and some of the limitations and advantages differ. The introduction of various reactive gases into the specimen chamber also allows chemical modification of the environment in which material is etched.

SEM of Subcellular Detail

SEM of internal cell structure may appear nonintuitive, given the familiarity of SEM images of whole cells and tissues viewed from the surface, but separation of cell contents (largely for biochemical analyses) has been an integral part of cell biology since its inception. Isolated organelles such as mitochondria or other vesicular components can be purified and visualized by SEM, or even a molecular level of purification for cytoskeletal elements such as tubulin, which can then be repolymerized *in vitro* to form intact microtubules and viewed by SEM. The resolution limits of FEG-SEM were pushed in the early 1990s by Martin Müller and colleagues, who produced stunning images of bacteriophage substructure, DNA, Fab fragments, and ultra-small immuno-gold particles (Hermann *et al.*, 1991). One of the earliest candidates for the enhanced 3D imaging provided by SEM was the chromosome, a robust structure due to the packaging ratio of 10 000:1 for the length of chromosome compared to the length of DNA contained within it. Whole chromosomes proved fairly impenetrable to early TEM studies producing a dense silhouette with a few individual looped fibers at the periphery. SEM of chromosomes that had been originally prepared for human karyotype analysis showed the whole structure in good surface detail. SEM imaging also revealed structural alterations along the length of the chromosome when LM staining protocols such as Geimsa were used to produce banding patterns to aid chromosome analysis. In the case of the Fragile X syndrome (which causes learning disabilities and cognitive impairment),

Figure 4 A simple method of visualizing internal cellular information by SEM. This tissue culture cell has been 'stripped' using adhesive tape. This procedure exposes both the nuclear surface (yellow) studded with nuclear pores (red) as well as internal nuclear chromatin (blue) on a base of cytoskeletal components after biochemical extraction of the remainder of the cytoplasm.

Figure 5 Chromosomes from a dividing muntjac cell in which the DNA was experimentally altered during replication, resulting in a structural difference between the chromatids which is clearly visible in SEM (courtesy C.J. Harrison).

the potential break point was precisely located by SEM studies (Harrison *et al.*, 1983). As with whole cell images, SEM images of chromosomes have proved popular for the majority of textbooks (Figure 5).

Freeze Etching

Another reason for the relatively late entrance of SEM into cell biology was the widespread use of surface replicas viewed in the TEM, which was (and still is) a popular technique for visualizing fine surface detail. These were made by evaporating a thin carbon film onto a surface of interest, and adding 'shadowing' contrast by evaporation of a heavy metal such as platinum at a low angle. The replica was floated off, and imaged in the TEM, providing images with depth perception not unlike SEM. Biological material was rapidly frozen, fractured with a cold razor blade, and then subjected to etching during which the surface water was removed by sublimation in a vacuum. At this point a replica was made, and the biological material thawed and removed – a technique known as freeze etching. As the fracture planes in frozen tissue would travel down membrane surfaces (which provide the easiest cleavage route), this technique, originally pioneered by Steere, and Moore and Mulethaler, and subsequently John Heuser, became widely used in cell biology (and still is). SEM was good for the more extreme topography of whole cell membranes (due to the very high depth of focus), but lacked equivalent resolution to the TEM, until the introduction of SEMs with FEGs and resolution of a few nanometers, which produce images with much the same resolution as TEM.

SEM and the Nuclear Envelope

Although early SEM images of the outer cell membrane were spectacular in their 3D detail, no new structure was discovered.

(a)

(b)

Figure 6 (a) High-resolution FEG-SEM image of the surface of an isolated nuclear membrane from the oocyte of *Xenopus laevis* (African clawed toad). Against the nuclear membrane itself (purple), each pore complex (gray) stands proud of the surface, bounded by short stubby projections. (b) Here the inside surface of the same material as (a) is imaged at a similar magnification (150 000 ×). The nuclear membrane (purple) shows an underlying orthogonal fibrous network, and each pore complex has a characteristic basket structure.

However, one area in which completely novel structure within the cell was shown by SEM was the nuclear envelope. This is a double membrane structure, regularly pierced by nuclear pore complexes (NPC), which are conduits of the continuously active exchange of material between nucleus and cytoplasm. For well over 30 years, NPCs appeared as little more than a break in the nuclear envelope with little associated structure when viewed in TEM thin sections, although Joe Gall had established an octagonal radial symmetry (Gall, 1967), extended into a 3D model by Hinshaw *et al.* (1992). Large areas of intact nuclear envelopes are easily dissected from the giant nuclei of amphibian oocytes, and when Hans Ris used FEG-SEM he found that the NPCs had a 'fishtrap' structure (subsequently the NPC basket) on their inside surface (Ris, 1997). Subsequent work by Goldberg and Allen, again using FEG-SEM went on to show further detail of the pore complex, and the presence of a fibrillar network attached to the baskets termed the nuclear envelope lattice (Goldberg and Allen, 1992; Figures 6(a) and 6(b)). Using a cell-free egg cytoplasmic extract system to incubate sperm heads, they showed stages in the formation of the NPC, and identified the roles of individual

Figure 7 An isolated *Xenopus* sperm head is incubated *in vitro* in extracted cytoplasm from an oocyte and rapidly forms a new nuclear membrane (green) over the surface of the chromatin (blue) before going on to replicate its DNA, imaged here by FEG-SEM at 50 000 $\times$ magnification. This type of experimental protocol produces material which would be difficult to image by other means, but at the same time generates unique information in the stages of nuclear pore formation (Goldberg *et al.*, 1997).

proteins (Goldberg *et al.*, 1997; Figure 7). Further work was extended to *in situ* studies in tissue culture cells, including details of the attachment of the HIV virus and its entry into the nucleus via the pore (Arhel *et al.*, 2007).

SEM in Cell Biology

For all the involved preparation (particularly when compared with straightforward fast freezing), it might appear to some that SEM in cell biology has reached its peak, but it retains many advantages, not least of which is the sheer area of material that can be covered – particularly important when only one NPC amongst five thousand on the surface of a nucleus may have an HIV particle attached. Labeling is sophisticated, with different sized markers allowing identification of several proteins at once, and the stability of the preparations (unlike frozen material) allows multiple reexaminations. Experimental cell free systems of component formation do not easily lend themselves to cryo methods, and although the cryo-aficionados will always point out potential artifacts from fixation, dehydration, and coating, remarkable similarities have been shown for almost all samples between cell biological SEM and other methods. For medium resolution work, some have even

suggested that techniques such as serial block face imaging and FIB-SEM could make the TEM redundant, restricting it to high-end applications such as cryo-EM tomography and single particle reconstruction. The role of SEM in cell biology is one which should continue to produce novel and high-quality results for many years to come.

Glossary

Correlative microscopy Correlative microscopy is a hybrid method to apply two different types of microscopy to the same view area of a specimen. In electron tomography, combination with a fluorescent light microscopy is used to locate the target of interest, based on genetically tagged fluorescent proteins or antibodies.

Cryo-EM Electron microscopy of frozen-hydrated specimens. In this article, we describe transmission electron microscopy (cryo-TEM), while scanning electron microscopy (SEM) and scanning transmission electron microscopy (STEM) are also applied to frozen-hydrate specimens. Cryo-TEM is one of common approaches to analyze three-dimensional (3D) structure of biological macromolecules and organelles.

Electron tomography Electron tomography is a method to reconstruct 3D structure from electron micrographs (which are 2D images). In electron tomography, a number

of micrographs are recorded from the identical objects (macromolecules, organelles, cells, etc.) by tilting the stage. While single-particle analysis reconstruct 3D structure by merging images from different particles, assuming they share the same 3D structure, images used by electron tomography are from one identical object. Therefore electron tomography is a potential method to analyze structure with heterogeneity, but radiation damage due to multiple illuminations limits the resolution.

Subtomogram averaging Subtomogram averaging is a computational technique to improve signal-to-noise ratio of 3D reconstruction. 3D volumes which cover the target (normally macromolecules), which are called subtomograms, are computationally extracted, aligned, and averaged. The macromolecules in the subtomograms must share the identical conformation. When there is heterogeneity, subtomograms must be classified.

Introduction

X-ray crystallography, NMR, and single particle EM provide a detailed view of biological macromolecules, allowing us to understand biochemical phenomena *in vitro* at atomic resolution. Now we have started exploring biological phenomena *in vivo* in cells or tissues, mainly at molecular but, in some cases, also at atomic resolution. *In vivo* function usually involves more molecules than the corresponding biochemical reaction *in vitro*, and thus requires the analysis of complex molecular networks. Electron tomography is a suitable approach to analyze such systems, since it allows visualization of complex biological three-dimensional (3D) structures in a noninvasive way. Therefore electron tomography can cover *in vivo* structural analysis, dynamics, and particles with irregular shapes (for example, virus with envelope). The potential targets of electron tomography are organelles, cells, and tissues, if they are sectioned to be thin enough ($<1\ \mu\text{m}$) for transmission electron microscopy (TEM). Molecules with high flexibility can also be a good target of electron tomography for dynamic studies taking advantage of 3D reconstruction without interparticle averaging.

The principle of 3D reconstruction from a number of 2D micrographs is the central section theorem. In single particle analysis many randomly oriented particles are illuminated only once and view angles are calculated under the assumption that they share the identical 3D structure. On the other hand, what is specific to electron tomography is the recording of micrographs from a single object at different tilt angles, which means that the electron-sensitive biological specimen is illuminated at multiple times. As a result, the resolution of electron tomography is not as high as in single particle

analysis. However, in electron tomography, specimens with heterogeneity or flexibility are accessible to 3D structural analysis.

Compared with other recently emerging techniques at intermediate resolution, such as super-resolution microscopy and block-phase SEM, electron tomography will be characterized as an imaging technique that can be applied to more intact specimens, in a noninvasive way and at higher resolution, but with narrower view areas.

In this section, we review the technique of electron tomography as a method to reconstruct biological molecular and cellular structures.

Specimen Preparation Methods

Electron tomography of biological specimens was introduced as a way to visualize intracellular 3D morphology with chemically fixed and stained samples, as well as samples prepared by high-pressure freezing and freeze substitution, both at room temperature (Frank, 1995; Parsons *et al.*, 1990). Although the latter method is sometimes referred to as 'cryo-EM,' it must be emphasized that the specimen is in the end embedded in plastic and kept at room temperature, which is different from cryo-electron microscopy discussed here (frozen hydrated without staining, Figure 1(a)). One difficulty of these methods, which in the end embed samples in resin, is the 30–50% shrinkage of the plastic section induced by the beam (Luther, 1992). Once the specimen is prepared for TEM, electron micrographs are recorded at the same area from various view angles, by tilting the specimen (Figure 1(b)). As an example, micrographs of the same eukaryotic flagellum,

Figure 1 Flowchart of cryo-ET. (a) Plunge freezing. The specimen in buffer is mounted on an EM grid (left), blotted by filter paper (center) and plunged into cryogen (right). The grid is blotted in a chamber with temperature and humidity controlled (top). (b) Scheme of tomographic data acquisition. The same object is illuminated multiple times from different orientation. The specimen shown is a ribosome (EMD2914) filtered at 5 Å resolution. (c) 3D reconstruction. Micrographs of an object (cilium) from various orientations are merged to reconstruct a 3D structure. (a) and (c) Modified from Ishikawa, T., 2015. Cryo-electron tomography of motile cilia and flagella. *Cilia* 4, 3.

prepared by plunge freezing, viewed from different angles are shown in [Figure 1\(c\)](#). Typical tomograms from flagella prepared by three different methods are shown in [Figure 2](#). While tomograms from stained samples (top and middle of [Figure 2](#)) show high contrast, periodic structure of flagella is maintained better in cryo samples without chemical embedding and staining (bottom).

Cryo-electron tomography (cryo-ET) is relatively new technique. Although the possibility to reconstruct the 3D structure of unstained biological specimens by electron tomography was already predicted in 1968 ([Hart, 1968](#)), it was realized much later – in early 2000s. One of the major challenges was data acquisition. At each tilt angle, the motion of the stage must be detected and the electron beam must be shifted to track the object of interest (a process called ‘tracking’). To minimize radiation damage, tracking and

focusing must be done automatically at a certain distance from the area of interest, and then the beam must be shifted back precisely to the area of interest. This process was facilitated by the development of high sensitivity and large view area digital cameras, stable stages, and computer control of the lens/coil currents. Another difficulty was to enhance image contrast from unstained images under extremely low-dose conditions. Since the density of biological molecules and vitreous ice is not so different, image formation relies mainly on phase contrast ([Amos et al., 1982](#)). Moreover, since specimens used for tomography are relatively thick, inelastic scattering of electrons causes a high noise level (the mean free path of inelastic scattering is ~200 nm). Field emission guns (FEG) and energy filters enabled imaging of such thick unstained specimen. Therefore the first 3D map of the interior of an eukaryotic cells was published only in 2002 ([Medalia et al., 2002](#)). In

(c) Ice embedding (cryo-EM) by plunge freezing (our unpublished result). Despite low contrast, structure is preserved without severe distortion.

this section, we review mainly cryo-ET and related techniques, but also show some examples of tomography from samples at room temperature.

The maximum specimen thickness for TEM is 0.5 μm (200 kV) to 2 μm (300 kV). Thick specimens ($>2 \mu\text{m}$) must be sliced to allow the transmission of electrons. Cryo-ultramicrotome and cryo-FIB are methods to slice thick ice-embedded specimen. Cryo-section (CEMOVIS) (Al-Amoudi *et al.*, 2004; Figures 3(a) and 3(b)), although suffering from artifacts during sectioning by cryo-ultramicrotome such as compression, knife marks, crevasses, and chatter (Al-Amoudi *et al.*, 2005) (mainly at a cellular level, and not so much in molecular structures (Pierson *et al.*, 2011)), has the advantage of allowing serial sectioning, which could facilitate tomographic reconstruction of whole tissues. Cryo-FIB (focused ion beam) milling (Figures 3(c) and 3(d)) is an emerging technique that uses a gallium beam and is expected to cause fewer artifacts than a diamond knife, and, therefore, provides tomograms that are more straightforward to interpret.

Methods of Cryo-ET

Here the author describes a general protocol for cryo-ET. For other methods of specimen preparation, please refer to Heuser (1981) (freeze-fracture deep etch replica) and Vanhecke *et al.* (2008) (chemical fixation, high-pressure freezing, and freeze substitution). Process of cryo-ET data collection and analysis is summarized in the supplementary video.

Specimen Preparation

In cryo-ET, the specimen must be embedded in vitreous (amorphous) ice. There are two methods of vitrification: for thin specimen ($<1 \mu\text{m}$) such as macromolecules, macromolecular complexes *in vitro*, organelles, and small bacteria, the specimen can be vitrified quickly (within microseconds) by plunge freezing (Figure 1(a); Dubochet *et al.*, 1988). Aqueous solution of molecules or cells is mounted on EM grids covered by holey or continuous carbon support. After removing excess liquid, the grid is plunged into liquid ethane at liquid nitrogen temperature. By currently available freezing devices, it is difficult to control or examine samples during the freezing on EM grids, especially interaction between molecules and carbon support is hard to control (Figure 1(a) bottom).

Thick specimen, such as large eukaryotic cells and tissues must be frozen by high-pressure freezing, in which the specimen is frozen within milliseconds under ~ 2000 bar pressure and then cryo-sectioned using a cryo-ultramicrotome (Al-Amoudi *et al.*, 2004).

Microscopy

For electron tomography in general, the specimen stage must allow a tilt of 60° or more. Programs for automatic data acquisition are available (e.g., SerialEM (Mastronarde, 2005); UCSF Tomo (Zheng *et al.*, 2010); TOM Toolbox (Nickell *et al.*, 2005)). Thick ($>200 \text{ nm}$) specimens require an energy filter (in-column or post-column). An energy filter allows to perform spectroscopic analysis (EFTEM) for elemental mapping as well (Comolli *et al.*, 2006; Messaoudi *et al.*, 2013).

For cryo-ET, each dataset must be recorded at low cumulative dose, i.e., at an extremely low dose for each individual micrograph. A FEG is indispensable to acquire phase contrast. Since tomographic data acquisition is a time consuming process (1 h for acquisition of one dataset), the use of a specially designed polepiece (cryo-polepiece) to minimize ice contamination is desirable. Detector companies, such as TVIPS, FEI, and Gatan, also provide their own data acquisition software. It is also necessary for a low-dose system (or minimum dose system) to focus and track objects at an area distant from the object of interest by shifting the beam during the tilt series data collection. The direction of the beam shift must be parallel to the tilt axis to keep the same focus in both areas. The amount of the defocus (2–15 μm) depends on the specimen thickness and the desired resolution. To pursue high resolution, a few studies attempted contrast transfer function (CTF) correction despite the difficulty to evaluate defocus from low-dose images from highly tilted objects (Philippson *et al.*, 2007).

Since it is not possible to tilt the stage 90° , there is always some information missing, a circumstance called ‘missing wedge’ (single axis) or ‘missing pyramid’ (dual axis) (Lucić *et al.*, 2005). Dual-axis cryo-tomography became possible with modern high-end microscopes, which have a system to rotate grids horizontally inside the column (Myasnikov *et al.*, 2013). The higher the angle at which data is collected, the less information is missed. The optimum increment tilt angle depends also on the specimen thickness and the desired resolution (Crowther *et al.*, 1970). Although the movement of

Figure 3 Two methods to slice frozen thick specimen. (a) and (b) Cryo-section (Bouchet-Marquis and Hoenger, 2011). (a) Sectioned frozen specimen (ribbon). (b) Electron micrograph. the stage during tilting is roughly tracked by the software, further alignment between micrographs within a tilt series is necessary. Normally, gold clusters (5–15 nm) are used as fiducial markers. Marker-free (fiducial-less) alignments have been successfully developed for stained sections (Winkler and Taylor, 2013). For cryo-ET, marker-free alignment is not common due to poor S/N, but there are attempts to develop algorithms of marker-free alignment for cryo-ET (Castaño-Díez *et al.*, 2007, 2010).

Tomogram Reconstruction and 3D Image Analysis

The aligned micrographs are merged into a 3D structure using R-weighted backprojection (Radermacher, 1988), SIRT (Zürner *et al.*, 2012), or ART (Messaoudi *et al.*, 2013). The reconstructed 3D tomogram suffers from poor signal-to-noise ratio (S/N), which is a direct evidence of the limitations of this technique. However, further structural information can be extracted by 3D image processing and the computational analysis of the tomograms. Denoising is a technique used to improve S/N and highlight structural features (Narasimha *et al.*, 2008; Figure 4(a)). Also, segmentation algorithms allow to distinguish two or more structures from a noisy tomogram (Frangakis and Hegerl, 2002; Figure 4(b)). For instance, synaptic vesicles and their connector and tethers have been

visualized by this method (Fernández-Busnadiego *et al.*, 2010; Figure 4(c)). Although these techniques can sometimes resolve features convincingly from noisy tomograms, they must be interpreted carefully.

Another approach to extract structural information from noisy cryo-electron tomograms is cross-correlation-based averaging. Volumes which involve target particles (called subtomograms), which supposedly share an identical 3D structure, are extracted, aligned in three-dimensions and averaged to improve S/N. The averaged structure from subtomograms extracted from even thick tomograms can reach ~25 Å resolution (Bui *et al.*, 2009). In this method, the main challenge is the proper extraction of subtomograms under noisy and heterogeneous environment, so they include the particles of interest. It is important to minimize the risks to average particles with different structures, or to extract at a wrong position or angle. This method is particularly suitable to analyze periodic structures inside cells or organelles, where subtomograms can be extracted based on periodicity, as shown for instance in eukaryotic axonemes (Bui *et al.*, 2012), and aligned with a roughly estimated Euler angle (Bui and Ishikawa, 2013). The technique of cross-correlation-based exhaustive search can be used to extract randomly distributed particles. To analyze heterogeneous environments (for example, cytoplasm with proteasomes and chaperones inside (Bohm *et al.*, 2000)), it is necessary to use a

multi-template-matching-based search. For averaging, particles can be classified into subclasses by cross-correlation between subtomograms and multiple templates (subtomogram classification). Classification is not straightforward because of poor S/N and missing wedges/pyramids. For this process, algorithms as cross-correlation-based template matching and unsupervised multivariate statistical analysis are used (Beck *et al.*, 2009; Frangakis and Hegerl, 2002; Figures 4(d) and 4(e)). Unsupervised subtomogram classification often suffers from the missing wedge: subtomograms are classified based on the orientations of the missing wedge, instead of structure. Supervised classification must be carried out carefully to avoid bias by templates.

Techniques to Combine with Cryo-ET

While electron tomography has been successful to visualize 3D structures of highly complex biological macromolecules and organelles, limited resolution is still a significant drawback. In spite of a few reports of tomographic analysis at resolution below 1 nm (Schur *et al.*, 2013), in general it is challenging to reach 2 nm resolution. Especially for thick specimen, resolution is usually limited to ~ 5 nm. To extend the applications to molecular level, it is essential to combine this technique with other methods that allow us to identify the molecules corresponding to the densities observed in the tomogram.

The direct way to identify molecules is either to increase density in a region of the tomogram by specific labeling or genetic tagging, or to decrease the density by a deletion mutant. As in standard immunoelectron microscopy, antibodies can be used to locate target molecules in the tomogram. When they are engineered as a small derivatives, this helps to locate component proteins in a complex (Meyerson *et al.*, 2013). However, the access of the antibody to organelles is often sterically limited. Genetic tagging to enhance density has been carried out, for instance, with ferritin (Wang *et al.*, 2011), biotin-streptavidin (Oda and Kikkawa, 2013; Oda *et al.*, 2014), and metallothionein (Diestra *et al.*, 2009). The use of tags that induce metal cluster formation, when applied to the cell, could cause artifacts and thus must be treated carefully. Deletion mutants have been used, for instance, to locate isoforms of dynein motor proteins in cilia (Bui *et al.*, 2008). However, in highly complex biological systems, which cryo-ET often addresses, genetic deletion of one component sometimes causes the loss of other components, and therefore does not really help us locate these proteins. Expression of a tagged protein in the deletion mutant generates a structure with the density of the target protein amplified, which enables its localization (Oda *et al.*, 2014).

Cryo-correlative light/electron microscopy (cryo-CLEM) is a technique that allows localization at low resolution, by recording fluorescent micrographs of tagged or fluorescently labeled molecules on the frozen grid. The method of CLEM is widely applied to image specimens at room temperature. Similarly to the regular TEM, immunolabeling can be applied to map molecules (Mari *et al.*, 2014). The instrument to embed the cellular specimen, and observe it simultaneously by light microscopy, is commercially available. Although cryo-stages to mount frozen grids for light microscopy are available

and a few successful works have been reported (Zhang 2013; Koning *et al.*, 2014), cryo-CLEM still has some barriers to overcome. One problem is the long working distance: to protect the objective lens, cryo-specimens must be kept at a certain distance from the lens, which limits the numerical aperture and, thus, hinders the detection of weak fluorescent signal. Another problem is the resolution of fluorescent microscopy. To address it, a recent study proposed a method to reach a range of nanometer resolution using multiple dyes (Schellenberger *et al.*, 2014). An additional approach to identify molecules in tomograms is to fit external information, either high-resolution structures from X-ray crystallography, single particle EM and NMR, or biochemical information of molecular connectivity, such as crosslinking, pull-down, immune-precipitation, and mass spectroscopy (Bui *et al.*, 2013).

Examples

The first cryo-ET of vitrified eukaryotic cells showed networks of actin filaments, as well as the ribosome and other features in the cytoplasm (Medalia *et al.*, 2002; Figure 5(a)). The arrangement of actin networks has been extensively studied by cryo-ET – remodeling of actin networks induced by infection of *Listeria monocytogenes* (Jasnin *et al.*, 2013). Interestingly, in studies of lamellipodia, two groups claim different results: actin networks with (Yang and Svitkina, 2011) and without (Urban *et al.*, 2010) branches (Figures 5(b) and 5(c)).

Until recently it was believed that bacteria had no cytoskeleton. However, cryo-ET has allowed to clearly visualize cytoskeletons inside the bacteria *Spiroplasma melliferum* (Kürner *et al.*, 2005; Figure 6(a)). This filament was later proved to be MreB, an actin homologue (Trachtenberg *et al.*, 2008). Since then, various bacterial cytoskeletons have been found and characterized by cryo-ET, for example, BtubA/B proteins form microtubule-like structure in *Prostheco bacter* (Pilhofer *et al.*, 2011; Figure 6(b)).

In the long history of structural analysis of spherical viruses by cryo-EM single particle analysis, this method has been virtually limited to symmetric capsid. Other component of the virus, such as tegument, membrane, and nucleic acids were not targets of 3D reconstruction, due to structural heterogeneity and flexibility. However, recent cryo-ET studies offered the possibility of 3D reconstruction of the whole virus (Grünwald *et al.*, 2003; Figure 6(c)).

The strong-binding interface of actin and myosin has been studied by single particle analysis of filaments reconstituted *in vitro* (Holmes *et al.*, 2003). However, actin/myosin interactions during contraction result in highly heterogeneous structures, which require tomographic analysis. Cross-bridges between actin and myosin filaments were studied using freeze-substituted and sectioned contracting insect flight muscle (Wu *et al.*, 2009). Subtomogram averaging allowed to visualize transition from weak-binding to strong binding of myosin heads to actin filaments (Wu *et al.*, 2010; Figure 7(a)).

Cryo-ET has provided insights into microtubule networks. Here we overview one example of a microtubule-based system:

cilia. Ciliary (or eukaryotic flagellar) '9 + 2' axoneme structure has been known for a long time. In motile cilia, dynein, microtubule-based motor proteins are the driving force, together with many other regulatory protein complexes. While, various EM techniques (negative stain, freeze-fracture deep-etch (Goodenough and Heuser, 1985), and section (Mastrorade *et al.*, 1992)) have been applied to reveal the molecular architecture of cilia, the first 3D reconstruction of the entire cilia structure was obtained by cryo-ET and subtomogram averaging. Dynein and regulatory proteins follow either 96 nm or 24 nm periodicity along microtubules, which allowed to perform subtomogram averaging (Ishikawa *et al.*, 2007; Nicastro *et al.*, 2006), and to distinguish the dynein structure in pre- and post-power stroke states (Lin *et al.*, 2014; Movassagh *et al.*, 2010). Also, comparison of mutant structures allowed to identify different dynein isoforms (Bui *et al.*, 2008, 2012; Figure 7(b)). Finally, this technique has permitted to reconstruct the structure of regulatory proteins (Heuser *et al.*, 2009; Pigino *et al.*, 2011).

Another successful example of the combination of cryo-ET, subtomogram averaging and hybrid approaches is the structural analysis of the nuclear pore complex (NPC). cryo-ET allowed us to visualize the 3D structure of the NPC embedded

in the nuclear envelope (Figure 7(c), left). The NPC has apparent eightfold symmetry, but, actually, this symmetry is somewhat perturbed. Recent progress in image quality and image analysis techniques have facilitated a symmetry-independent alignment and averaging (Maimon *et al.*, 2012). The most recent tomographic analysis reached 32 Å resolution (Figure 7(c), center) and, combined with single particle analysis, chemical crosslink and mass spectroscopy, allowed the assignment of component molecules (Bui *et al.*, 2013; Figure 6(c), right). Furthermore gold-labeling demonstrated distribution of cargo-transporters (Figure 7(c) right bottom; Beck *et al.*, 2007).

Future Outlook

There are numerous on-going efforts to further develop electron tomography and expand it to explore new directions. One of the main issues is the improvement of resolution, especially for thick specimens. In the related technique of single particle analysis, another major method of electron microscopy, recently developed direct electron detectors, which replace negative and conventional charge-coupled device (CCD) or complementary metal-oxide-semiconductor (CMOS) cameras with scintillators, have represented a breakthrough that has enabled *in vitro* structural analysis at near-atomic resolution (Li *et al.*, 2013). Nevertheless, it is not yet clear how much contribution this type of detectors can bring to cryo-ET. On the one hand, improved S/N from the direct detector at high-resolution range will enable a more precise alignment, maybe at lower dose. However, drift correction, another advantage of direct detectors, may not be as effective as single particle analysis, since the exposure time of tomography is, due to extraordinary low dose, relatively short.

To compensate the limitation in resolution, there are attempts to further develop tagging and labeling techniques for molecular identification. These developments will be tightly linked to new methods of genetic engineering, such as knockout, knockdown by various RNAi, and protein expression techniques.

To handle eukaryotic cells and tissues noninvasively, i.e., without sectioning or milling, we need a breakthrough in the field. For thick samples (> 2 µm), TEM with higher accelerating voltage will be useful, once FEG and detectors for high voltage are developed. X-ray tomography is capable of non-invasive 3D visualization of whole cells and tissues. Soft X-ray tomography using zone-plate imaging technique reaches ~10 nm resolution of up to 5 µm thick specimen (Hagen *et al.*, 2012; McDermott *et al.*, 2012; Weiner *et al.*, 2013). Combination of X-ray tomography for the entire cells/tissues and electron tomography for sections could enable high-resolution imaging of the entire cells/tissues.

With the current imaging strategy using phase contrast, we need a large defocus to improve contrast of, especially, ice-embedded thick specimens, which degrade resolution. To overcome this problem and collect images at near-focus condition, the use of phase plates has allowed us to obtain good contrast without a large defocus. For instance, cryo-ET using Zernike phase plate provided amazingly high contrast (Fukuda

Figure 7 Various intracellular structures revealed by electron tomography. (a) Electron tomography of rapidly frozen, freeze-substituted, and sectioned insect flight muscle. Left: section of the tomogram (Wu *et al.*, 2009). Right: one 3D structure of cross-bridge after subtomogram classification and averaging. Atomic models of myosin, actin, and regulatory proteins are fitted (Wu *et al.*, 2010). (b) Axonemal structure from cilia/flagella by cryo-electron tomography (cryo-ET). Left: view of the whole '9 + 2' structure. Right: one microtubule doublet extracted from the '9 + 2' structure. Gray: microtubule. Red and cyan: dynein motor proteins (Bui *et al.*, 2008, 2012). Blue: radial spoke (Pigino *et al.*, 2011). Green: dynein regulator complex (Heuser *et al.*, 2009). (c) Nuclear pore complex by cryo-ET. Left: NPC embedded in nuclear envelope (Maimon *et al.*, 2012). Center: 32 Å resolution structure of human NPC (Bui *et al.*, 2013). Right top: molecular identification by fitting single particle analysis and mass spectroscopy data (Bui *et al.*, 2013). Right bottom: distribution of transporter revealed by gold-labeling and tomography (Beck *et al.*, 2007).

and Nagayama, 2012; Danev *et al.*, 2014). Another possibility is STEM tomography, with which all the data, including data from highly tilted specimen, could be collected without any defocus.

Future developments in electron tomography will fill the gap between X-ray crystallography or NMR and light microscopy, which will allow us to visualize detailed 3D structures of biological macromolecules *in vivo* at nanometer resolution.

Glossary

Freeze-fracture Cell or tissue samples are rapidly frozen by HPF or plunge-freezing and then fractured at low temperature. The fracture faces are then replicated by vacuum evaporation of platinum and carbon. After thawing, the replicas are cleaned and viewed in the TEM.

Freeze-substitution Frozen samples are dehydrated at 183 K (−90 °C) by removal of ice with acetone ('substitution'). The freeze-substitution cocktail contains fixing reagents such as uranyl acetate or glutaraldehyde. For purely morphological investigations, OsO₄ is often included in the substitution cocktail. Samples can be embedded at low temperature by resin polymerization with UV light in case Lowicryls are used, or at room temperature with heat-cured resins such as LR White.

High-pressure-freezing (HPF) Cryo-immobilization (also called cryo-fixation) procedure by which 2.045×10^8 Pa

(2045 bar) are applied simultaneous with the cryogen (LN₂) to suppress ice crystal nucleation and slow down ice crystal growth. Vitreous ice formation (ice without crystals) is only achieved in tiny samples (approximately 200 μm in height).

Progressive-lowering of temperature (PLT) The chemically fixed sample is cooled in a stepwise manner following the dehydration steps to 248 K (−35 °C), infiltrated with the resin and polymerized at low temperature by UV light. Suitable resins are LR Gold or Lowicryls.

Tokuyasu cryosectioning method Chemically fixed samples are infiltrated with 2.3 M sucrose, frozen in LN₂, and sectioned at 163 K (−110 °C) in a cryo-ultramicrotome. During pickup from the dry and cold knife and transfer to a TEM grid the sections are thawed and can be used for immunolabeling.

Introduction

For the understanding of cellular processes such as internalization of molecules, intracellular transport during endocytosis or in the biosynthetic pathway, knowledge about the site of action is crucial. Electron microscopy provides means to study the localization of molecules at high resolution in the context of the cellular environment. Here suitable probes such as antibodies are applied to the sample and then visualized with electron-dense markers. In principle, these particulate markers indicate the place where the specific probe is bound to the molecule of interest. This could be a plasma membrane receptor, an internalized ligand, an organelle-specific protein, or even a lipid. Since the marker is visualized on an ultrathin section in the transmission electron microscope (TEM), all the other structures are also visible by their contrast (Figure 1). Contrast formation in the TEM occurs by scattering the electrons of the incident beam while passing through the section, which can be increased by heavy metals introduced into the sample during the sample preparation. Therefore, samples for TEM undergo a sequence of preparation steps which starts with the immobilization/fixation of the living sample and end in a dry and very thin section in vacuum. In this article we will give an overview of the different approaches for sample preparation before discussing strategies in immunoelectron microscopy such as preembedding or on-section labeling using cryo- or plastic sections, whole mount, and replica labeling. Furthermore we will mention correlative light and electron microscopy (CLEM) methods and touch in the end aspects of immunogold label quantification.

Sample Preparation Strategies

The ultimate goal of sample preparation is the preservation of the structural and chemical composition of a cell as it is in the living state. Unfortunately, this is hardly possible, because any treatment of cells or organisms provokes changes which are difficult to control or assess. So our efforts rather produce approximations which have to be controlled by independent methods. For visualization by electron microscopy samples have to comply with electron bombardment under high vacuum conditions. As a consequence for most applications the sample needs to be stabilized or fixed and dehydrated. Both, the method of fixation as well as of dehydration, are potential sources of artefacts which are deviations from the natural state. It is widely accepted that cryo-immobilization by high-pressure-freezing (HPF) and subsequent dehydration/fixation by freeze-substitution and embedding at low temperature represents the best approach for structural preservation of small specimens (up to 200 μm sample thickness and 2 mm in diameter). But in many cases, for example for larger specimens, chemical fixation is a useful sample preparation tool for successful immunoelectron microscopy studies while keeping a critical eye on possible fixation artefacts. As depicted in Figure 2 several sample preparation strategies are applicable for immunoelectron microscopy. For further reading we recommend a recent article by McDonald (2014a).

Chemical Fixation

Aldehydes such as formaldehyde and glutaraldehyde react with amino groups in the sample and induce protein

Figure 1 Immunoelectron microscopy provides information about the localization of antigens with high spatial resolution. The cellular context and the structure of the organelles, the so-called reference space, are visible. (a) Immunolabeling of catalase identifies peroxisomes in hepatocytes of rat liver. The primary rabbit antibody is detected with protein A-gold conjugates on ultrathin cryosections. m, Mitochondrium. Bar: 500 nm (b) Golgi complex in a mouse spinal cord neuron. Immunolabeling of a cryosection shows the localization of a γ -adaptin-positive vesicle (arrow) budding from the trans-Golgi network (TGN). g, Golgi complex. Bar: 200 nm.

Figure 2 Sample preparation strategies for immunoelectron microscopy.

cross-linking. Higher concentrations of aldehydes result in stronger cross-linking and an improved structural preservation, but unfortunately the ability to localize antigens declines accordingly. To maintain antigenicity, for immunocytochemistry mostly low concentrations of glutaraldehyde (0.1–0.2%) in combination with formaldehyde (2–4%) are used at the cost of the structural preservation. Depending on the nature of the molecules in the sample and the sample size fixation takes between seconds or minutes for cultured cells to up to several hours for tissue. Some cellular constituents such as small proteins or molecules like neurotransmitters are difficult or impossible to fix. It is advisable to fix cultured cells by adding double-concentrated fixation solution directly into the culture dish with the cells in their warm medium to minimize disturbance of the cell's physiology before fixation. Then, after several minutes, the fixative-medium mixture is replaced by fresh fixation solution. For tissue immersion fixation or perfusion fixation are possible. To our experience some tissues like mouse optic nerve or peripheral nerves are very well preserved by immersion fixation. Other organs such as liver or pancreas require perfusion fixation for optimal results. In addition to this for every type of sample the suitable buffer vehicle needs to be determined. Since the reaction of aldehydes with proteins produces H^+ , the vehicle buffer should have a high buffer capacity. Ideally, the osmolality of the buffer is adjusted to the physiological demands of the tissue of interest. Unfortunately, this can only be a rough approximation, because the osmotic properties within a tissue or even a cell can vary significantly. For immunocytochemistry in general, the duration of the fixation should be minimized. The antigenicity of proteins declines with the incubation time. Therefore, in sensitive cases the duration of fixation can be even limited to 1 h. After fixation the samples can be stored in 1% formaldehyde at 4 °C until further processing. We kept samples under these conditions for more than 10 years without recognizable loss of antigenicity. For further reading about the chemistry and application of fixing agents the book by Griffiths, 1993 is recommended.

Plastic Embedding or Cryosectioning of Chemically Fixed Samples

Ultrathin sectioning requires hard blocks. This can be achieved by embedding in plastics which are hardened by polymerization. Freezing is another way of hardening a sample. This approach is applied for ultrathin cryosectioning according to Tokuyasu by embedding the samples in a frozen sucrose solution (Tokuyasu, 1980). The advantage of plastic embedding is the ease of sectioning and handling. In principle, the sample can be dehydrated at room temperature and embedded in plastic which is cured by heat or with an accelerator. One popular resin for this application is London resin (LR) White (Newman *et al.*, 1983). Another approach for plastic embedding of chemically fixed samples is the so-called progressive-lowering of temperature (PLT) protocol. Here, the sample is cooled in a stepwise manner following the dehydration steps to 248 K (–35 °C), infiltrated with the resin and polymerized at low temperature by UV light. Suitable resins are LR Gold or Lowicryl K4M and HM20 which were designed for low

temperature polymerization. The rationale here is the assumption that dehydration and resin polymerization at low temperatures induce fewer changes to antigens compared to processing at 4 °C or room temperature, since at low temperature less molecular movement occurs. Many of these protocols and resins are discussed in Newman and Hobot (1999). Detailed protocols describing PLT methods are also available (Cavalier and Spehner, 2009).

The Tokuyasu technique of ultrathin cryosectioning and immunolabeling does not require dehydration and embedding. Here, the chemically fixed samples are infiltrated with 2.3 M sucrose, mounted as tiny blocks on aluminum sample pins and frozen. These blocks are cut in a cryo-ultramicrotome at –110 °C, ultrathin sections are picked up with a small droplet of pickup solution (Liou *et al.*, 1996), thawed and transferred onto a carbon-formvar-coated TEM grid which could either be used directly for immunolabeling or stored at 4 °C (Griffith and Posthuma, 2002). In this approach any incubation with organic solvents and embedding in plastic resins are avoided and the sections on the TEM grid remain hydrated until the very last drying step after immunolabeling. Therefore, the Tokuyasu approach became popular and is applied successfully until today. For the experienced user of special equipment (cryo-ultramicrotome, cryo-immuno diamond knife, and other tools) this is a very quick method. But, apart from the pure handling also the interpretation of the cryo-immuno data at the TEM requires experience. As pictured in Figures 3(a) and 3(b) the contrast of cellular structures differs from plastic embedded samples (Figures 3(a) and 3(b): comparison of plastic and cryosection). This method is very well suited for membrane structures, but cytoskeletal elements are often insufficiently visible. Due to the lack of any embedding medium, the surface of cryosections is rougher and thereby provides good accessibility for the probes. Moreover, the antigens remain fully hydrated and immersed in the incubation solutions and are better recognized by the antibodies due to less denaturation. For further reading Peters and Piereson (2008) and Slot and Geuze (2007) are recommended.

Cryo-Immobilization and Freeze-Substitution

Fixation implies immobilization. By HPF the specimen is immobilized by purely physical means within milliseconds due to cooling with liquid nitrogen (LN_2). Ideally, the process of freezing preserves a snapshot of all cellular components in the live state. The application of approx. 2.045×10^8 Pa (2045 bar) simultaneous with the cryogen slows down the process of ice crystal nucleation and growth. In the best case, the freezing occurs quicker than the ice crystal formation resulting in so-called amorphous or vitrified ice in samples of approx. 200 μm thickness (Dubochet, 2007). Also at ambient pressure samples can be cryo-immobilized by other techniques such as plunge-freezing where thin samples are rapidly frozen by plunging into liquid propane at LN_2 temperature. In comparison to HPF the zone of vitrified ice is here significantly thinner and mostly confined to 10–20 μm . After obtaining a perfectly frozen and fully hydrated specimen at LN_2 temperature, several processing options are possible. The samples can be used for freeze-fracture cytochemistry as outlined below or

Figure 3 Influence of sample preparation method on the appearance of myelin in mouse optic nerve samples. In conventional plastic embedded samples membranes appear black and cytoskeletal elements like microtubules are clearly visible. In Tokuyasu cryosections membranes appear white. Axonal microtubules are hardly visible. Cryo-prepared samples have a well-preserved ultrastructure. This is especially true for myelin. Here, distortions of the tightly wrapped myelin membranes are avoided. However, cryosections of high-pressure frozen and rehydrated freeze-substituted optic nerve show only sparse labeling. Moreover, the myelin structure appears changed by the dehydration with acetone. (a) Mouse optic nerve fixed by immersion into 2.5% glutaraldehyde and 4% formaldehyde in phosphate buffer at pH 7.2 and subsequently embedded in Epoxy-resin following standard procedures. Bar: 500 nm. (b) Tokuyasu cryosection of a chemically fixed mouse optic nerve (4% formaldehyde and 0.2% glutaraldehyde). Immunogold labeling shows the presence of proteolipid protein (PLP) in the myelin sheath. Bar: 500 nm. (c) Mouse optic nerve prepared by high-pressure-freezing and freeze-substitution followed by Epoxy-resin embedding. Myelin structure is far better preserved, bar: 500 nm. (d) Tokuyasu cryosections after HPF, freeze-substitution and re-hydration for cryosectioning. Immunolabeling demonstrates PLP in compact myelin. Bar: 200 nm.

directly visualized by cryo-imaging techniques such as cryo-TEM after cryosectioning (cryo-electron microscopy of vitreous sections (CEMOVIS) (Al-Amoudi *et al.*, 2004)) or cryo-scanning electron microscopy (cryo-SEM, (Walther and Müller, 1999)) also in three dimensional (3D) using a focused ion beam (cryo-FIB-SEM, (Schertel *et al.*, 2013)).

For immunoelectron microscopy incubation with antibodies at room temperature is required, so the frozen samples have to be transferred somehow to ambient temperature. For this purpose they are stabilized chemically, dehydrated, and embedded in a resin for ultrathin sectioning. In a process called freeze-substitution the ice is removed at 183 K (-90°C) by organic solvents, mostly acetone. The freeze-substitution cocktail usually contains stabilizing and fixing reagents. This could be glutaraldehyde and also uranyl acetate. For Lowicryl-embedding OsO_4 is hardly used, but it has been shown in a study applying Tokuyasu cryosectioning after freeze-substitution that 1–2% OsO_4 in the substitution cocktail did not influence the immunolabeling but increased

membrane contrast (van Donselaar *et al.*, 2007). After a certain time span at 183 K the temperature is raised. It is not well studied how efficient fixatives react at low temperature. However, it was shown by Humbel *et al.* (1983) that glutaraldehyde cross-links bovine serum albumin (BSA) in solution within 1 h at 263 K (-10°C) and within 4 h at 243 K (-30°C).

In the end, the samples are infiltrated with the resin at low temperature (228 K/ -45°C) and polymerized by UV illumination. A typical resin for this procedure would be Lowicryl HM20. Alternatively, the temperature is allowed to reach 277 K (4°C) or room temperature for resin infiltration and polymerization by heat or accelerator, which can be done, for example, by using LR White. A plethora of all kinds of different published protocols is available. However, recent studies have shown that protocols can be simplified drastically for many samples in terms of procedure and equipment (McDonald, 2014a,b). These references are also recommended for further reading on sample preparation. Samples can also be

rehydrated after freeze-substitution and processed for Tokuyasu cryosectioning and immunolabeling if plastic embedding needs to be avoided (Ripper *et al.*, 2007; van Donseelaar *et al.*, 2007; Figure 3(d)).

In comparison to chemical fixation, conventional dehydration, and embedding, this cryopreparation methodology results in structural preservation that far better represents the natural state (compare Figure 3). This might be explained by several important characteristics of cryopreparation: First, the immobilization occurs very fast (in milliseconds) and purely physical without chemical modification of the samples. Second, the immobilization step is separated from the process of fixation or stabilization. This means, all movements have been stopped by freezing, so the fixation takes place in an immobilized sample. Related to this, the diffusion of the fixing reagents occurs prior to the fixation process, since the chemical reactions happen efficiently only during the warm-up phase after substitution and diffusion have been completed. Last, dehydration is performed at low temperature by removal of ice, which is a solid. This process is not well described, but it seems to differ fundamentally from extraction of water from a wet sample resulting in smaller aggregates than in conventional dehydration. Taken together, these properties help avoiding or at least limiting aggregation, shrinkage, extraction of material, and collapse of structures, which are common artefacts of conventional processing (Kellenberger, 1987).

Immunolabeling Strategies

At the beginning of the experiment several strategic decisions have to be made depending on the scientific question: What kind of antigen will be localized? Is it a cytoskeletal protein, a membrane receptor, a transmembrane or membrane-associated protein, a cytosolic antigen, or a lipid? Then, what kind of probe am I going to use? Is it an antibody or another probe like a recombinant binding protein? From which species is the antibody I am planning to use? How likely are the epitopes of the target molecule exposed *in situ*? Depending on all these aspects not only the most suited sample preparation method but also the labeling strategy has to be chosen: preembedding or on-section labeling, whole mount labeling, or freeze-fracture immunocytochemistry.

Preembedding- and On-Section Labeling

In the preembedding labeling approach the whole sample or a large piece of it is incubated with the labeling probes and then embedded, sectioned, and viewed in the TEM (Figure 4). For on-section labeling, also called post-embedding labeling, the sample is fixed and then further processed for sectioning. This could be embedding in Lowicryl or preparation for ultrathin cryosectioning according to Tokuyasu. Then the sectioning is performed and subsequently the sections are incubated with the probes (Figure 5). In comparison to preembedding labeling, the on-section labeling approach is more flexible, since it offers several options for the fixation method ranging from chemical aldehyde fixation to cryopreparation methods as described above.

For preembedding labeling the sample requires chemical fixation which consists usually of a combined formaldehyde

Figure 4 Preembedding labeling: samples are fixed chemically and permeabilized to allow diffusion of antibodies into the sample. After immunolabeling the sample is embedded in plastic, sectioned, and viewed in the electron microscope.

Figure 5 On-section labeling: samples are prepared following the sample preparation method of choice which could be chemical fixation or cryopreparation by HPF and freeze-substitution. After embedding and sectioning, immunolabeling is performed on the sections.

and glutaraldehyde solution in a suitable buffer at suitable pH. The amount of glutaraldehyde, if any, should be low (0.1–0.2%) since this di-aldehyde is cross-linking proteins to a

higher extent than formaldehyde, which is a mono-aldehyde. The extent of cross-linking negatively influences labeling efficacy, because antigens are masked, modified, or become inaccessible to the probe. Furthermore, preembedding labeling requires permeabilization of the sample to permit access of the probes. There are different permeabilization protocols ([Humbel et al., 1998](#)), for example, the use of detergent such as Triton X-100 or saponin, application of NaBH_4 which is a reducing agent used for antigen retrieval, because it breaks fixative-induced double bonds. Another possibility is freezing/thawing which is a purely physical method using ice crystals for permeabilization. The latter has the advantage that it avoids lipid extraction which could happen by application of detergents.

In the next step, the permeabilized sample is incubated with primary antibodies or other probes. Since the diffusion distance can be several micrometers, incubation times are long to permit sufficient infiltration of the probes into the sample. The incubation time with the primary antibody lasts typically several hours or takes even overnight. Accordingly the washing steps to remove unbound probe have to be long as well. Then the secondary antibody or probe is applied. This probe carries the electron-dense marker for visualization in the TEM. For preembedding labeling it is recommended to use antibodies/probes conjugated to ultra-small colloidal gold particles. These gold particles have a size of only a few nanometers in diameter and therefore they are small enough to allow efficient diffusion of the secondary probe into the sample. Because 2–3 nm gold particles are not well visible in standard TEM, these gold particles are enlarged by a so-called silver-enhancement procedure ([Bienz et al., 1986](#); [Yi et al., 2001](#)). After these procedures the sample is embedded in epoxy following a standard-embedding protocol, sectioned, and viewed in the TEM ([Figure 4](#)). Preembedding labeling is useful for surface labeling of whole organisms such as bacteria or living cells. In this case permeabilization and long incubation times are not required. These samples can also be visualized in the scanning electron microscope (SEM). Moreover, preembedding labeling can be applied for 3D immunolocalization ([Morphew, 2007](#)). This reference is also recommended for further reading. Except for pure surface labeling the disadvantages of this approach are the negative effect of permeabilization on the preservation of the ultrastructure and the practical limitations regarding sample preparation.

In on-section labeling antibodies or probes are applied to thin sections of the sample under investigation ([Figure 5](#)). Similar to preembedding labeling the sections are first incubated with the primary antibody/probe and then visualized with an electron-dense marker like IgG-gold or protein A-gold. Since the probes interact mostly only with the surface of the section, diffusion distances are short and therefore incubation times much shorter than in preembedding labeling. A typical labeling protocol is described in [Figure 6](#). The procedure starts with inactivation of residual aldehydes from the chemical fixation, continues with a blocking step to prevent nonspecific sticking of the probes to hydrophobic sites or charges in the sample using BSA, which is then followed by the primary antibody incubation in blocking buffer for typically 30 min to 1 h. Next, the secondary gold-conjugated probe is applied. On cryosections we often use protein A-gold which binds to rabbit IgG (immunoglobulin G) antibodies. Secondary probes are available coupled to different sizes of colloidal gold ranging

from 2 to 40 nm in diameter. Gold-conjugated secondary antibodies (IgGs) are preferred for labeling of Lowicryl sections. For the localization of two different antigens in the sample these two gold sizes allow double-labeling procedures. Also secondary antibodies coupled to ultra-small gold particles can be used. As already mentioned these require enlargement by silver enhancement. For further reading compare [Stierhof \(2009\)](#). In the end the sections are stained with heavy metals and dried before examination in the electron microscope. As already mentioned in the sample preparation section, on-section labeling can be performed on plastic sections or cryosections according to Tokuyasu. Plastic embedding requires dehydration, resin infiltration, and polymerization. During dehydration with organic solvents, extraction and displacement of cellular components can occur. Also membranes are modified, since the lipids are washed out as well. Plastic sections are rather stable, but the resin is also masking antigens. In comparison, Tokuyasu cryosections are resin-free. Therefore, antigens are better accessible. The lack of dehydration by organic solvents makes Tokuyasu cryosections suitable for lipid labeling ([Möbius et al., 2003](#)). But cryosections are also very fragile, because they consist only of the biological material. This can result in loss and also displacement of material in the critical moment when the cryosection is thawing after section pick-up. For the integrity of cryosections the composition of the pick-up solution matters ([Liou et al., 1996](#)).

Whole Mount Labeling

In some cases sectioning is not required for EM-immunocytochemistry. A whole mount preparation of a fibroblast-like cell from chicken embryos published in 1945 illustrates the early days of electron microscopy as a tool to study cell biology ([Porter et al., 1945](#)). The cell was grown on a thin film which was then transferred to a TEM grid and viewed in the electron microscope. Viewing parts of the cell as a whole hence not sectioned can be advantageous for studying complex organelles with branched tubular-vesicular morphology, since information about the 3D organization is often hard to retrieve from thin sections. A method for whole mount immunoelectron microscopy was developed and used successfully to study exit pathways from the endocytic system, which is characterized by a complex tubular morphology ([Stoorvogel et al., 1996](#)). For this purpose, cells are grown on formvar-coated golden TEM grids, incubated with transferrin coupled to horseradish peroxidase (Tf-HRP) for 1 h to specifically target endosomes followed by incubation with diaminobenzidine (DAB), H_2O_2 , and ascorbic acid. By this protocol, the freely diffusing DAB is polymerized only in the endocytic system. Polymerized DAB traps by cross-linking the protein content of the endosomes and makes the entire organelle visible by the electron-dense precipitate. Then, cells are permeabilized to remove the cytosol, immunolabeled, and prepared for TEM by critical point drying. As shown in [Figure 7](#) vesicular tubular endosomes of HeLa cells are visualized with the Tf-HRP DAB method and double labeled for clathrin and cholesterol. Clathrin, indicated by 15 nm gold particles, is mostly detectable on buds, while cholesterol, visualized by using biotinylated perfringolysin ([Möbius et al., 2002](#)) and 10 nm

Figure 6 On-section immunolabeling protocol.

Figure 7 Whole mount labeling of vesicular tubular endosomes in Hela cells: The endocytic system was specifically filled by uptake of HRP-coupled TfR and subsequent DAB-reaction. After permeabilization double-immunolabeling of clathrin (15 nm gold) and cholesterol (10 nm gold) was performed. (a) Clathrin labeling is mostly found of buds, cholesterol labeling localizes also to tubules. (b) Sometimes adjacent buds are exclusively labeled for clathrin or cholesterol (arrows). Bar: 200 nm.

gold particles, is also localized to the tubular parts of the organelle. The whole mount immunolabeling method turned out to be especially useful to study processes which involve changes in the overall morphology of the endocytic system (Kleijmeer *et al.*, 2001). The method is also useful for the visualization of epitopes on viruses, bacteria, vesicles, or anything small that could be mounted directly onto a TEM grid.

Freeze-Fracture Replica Labeling

Another technique that localizes molecules to structures independent of thin sectioning is freeze-fracture cytochemistry. Here, samples are frozen, freeze-fractured and then prepared in such a way that a planar view on membrane fracture faces are created. In combination with immunolabeling this represents a powerful tool to study the size and shape of membrane domains and the lateral distribution of integral membrane proteins within a complex sample.

For freeze-fracture applications specimens can either be fixed chemically and then frozen after treatment with cryoprotectants such as glycerol or directly fresh frozen by HPF. The sample is then fractured in frozen state (at -100°C or lower). The fracture of the sample occurs usually at the weakest parts so that the fracture plane runs along the hydrophobic interior of membranes splitting them into the two leaflets and thereby exposing integral membrane proteins. This newly created fracture face is stabilized and replicated by vacuum-deposition of platinum and carbon. Before this coating an optional 'etching'-step could be included involving ice sublimation to expose more cellular structures which are buried in the ice. Without immunolabeling this replica is then cleaned by incubation with strong acids or sodium hypochloride solution so that the biological material is completely removed before examination in the TEM. For the description of the visible structures a specific freeze-fracture nomenclature was developed (Branton *et al.*, 1975; Figure 8). The lipid bilayer of a membrane consists of two membrane leaflets: the E-half facing the extracellular space and the P-half facing the protoplasm of the cell. After splitting the bilayer into the two leaflets by freeze-fracturing, the E-half has a side facing the extracellular space called E-surface (ES) and a side facing the now exposed interior of the membrane called E-face (EF). Correspondingly, P-surface (PS) describes the cytoplasmic surface of the membrane and P-face (PF) the artificially created fracture face of the inner side of the cytoplasmic leaflet. The P-half of the membranes faces the cytoplasm, the nucleoplasm, and

the matrix of mitochondria or chloroplasts. The E-half is in contact with the extracellular space and the topologically equivalent lumen of all single-membrane enclosed organelles.

Various techniques have been developed to combine freeze-fracturing with immunocytochemistry which can be grouped into three categories depending on the order of preparation steps:

'Fracture-label': immunolabeling is performed after freezing, freeze-fracturing, and thawing of the samples in aldehyde fixing solution. The exposed membrane halves are then accessible to the labeling probes. The resulting sample can be further processed by embedding and thin sectioning or by preparing replicas. For replica processing the labeled samples need to be dried either by critical point drying or freeze-drying before evaporating platinum-carbon on them. After the coating procedure, the biological material is removed leaving only the gold label on the replica. A disadvantage of this approach is that during thawing in aqueous fixation solution a reorganization of the fractured membrane halves into discontinuous bilayers occurs exposing more antigens than those in the original fracture plane. Also the typical freeze-fracture morphology is lost. Moreover, the effect of fixatives on the antigenicity has to be considered.

'Label-fracture': here a suspension of cells is immunogold labeled at the surface, then frozen, freeze-fractured, and replicated. The replica is then only washed with distilled water, so that biological material remains attached. Only in places where the sample was fractured concavely exposing the E-half with the label on the E-surface, the sample is thin enough for the electron beam to reveal the gold particles. Areas with convexly fractured cells still contain too much biological material for visualization of any detail in the TEM. An obvious limitation of this method is the restriction to cell surface labeling and therefore to studies of the E-half.

'Freeze-fracture replica labeling' (FRL): the invention of this technique by Kazushi Fujimoto (Fujimoto, 1997) was a major leap forward in freeze-fracture cytochemistry. Here, non-fixed samples are rapidly frozen by HPF or plunge-freezing with or without pre-treatment with glycerol, fractured, and replicated. Then the biological material is partially removed by prolonged treatment with 2.5% SDS. This leaves behind lipids and membrane proteins attached to the replicas (Figure 9). By this technique any membrane-associated antigen such as caveolin-1 (Figure 10) is well accessible for immunolabeling. The combination of structural information of large membrane regions from the replica with essential information about the

Figure 8 Freeze-fracture nomenclature: the fracture plane tends to follow the inner core of biomembranes splitting them into a cytoplasmic and an extracellular leaflet and exposing the inner side of each leaflet.

Figure 9 Freeze-fracture replica labeling: after rapid freezing by HPF or plunge-freezing samples are fractured ((a) and (b)). The fractured faces are then replicated by deposition of carbon/platinum layers (c). After reaching room temperature the biological material is partially removed by prolonged treatment with 2.5% SDS. This leaves behind lipids and membrane proteins embedded in the platinum-carbon cast which are well accessible for immunolabeling (d).

Figure 10 Freeze-fracture and freeze-fracture replica labeling: (a) freeze-fractured *Bacillus subtilis*. Fracturing exposed the membrane interior revealing the two inner faces of the membrane leaflets: the convex P-face (PF) of the cytoplasmic leaflet and the concave E-face (EF) of the extracellular leaflet on an adjacent bacterium. composition regarding proteins and lipids contributed substantially to our understanding of many aspects of cellular biology (Severs and Robenek, 2008; Möbius *et al.*, 2010).

CLEM

Electron microscopy offers high resolution imaging at sub-cellular scale, but light microscopy gives an overview of a complex tissue, visualizes processes in living samples, or helps localizing single rare events. The combination of different imaging modalities to examine the same sample in a correlative manner provides more information than any result achieved with only one imaging technique alone. The resolution limit of light microscopy has been overcome by the development of super-resolution fluorescence microscopy techniques. But this is only true for fluorescent signals. For a complete interpretation of localization data, the visualization of the so-called reference space is crucial. The reference space defines the unlabeled cellular context, which remains invisible

in fluorescence microscopy (Griffiths, 2001). This reference space is contributed by electron microscopy.

For CLEM different approaches and levels of complexity are possible. Not all of them necessarily require immunoelectron microscopy. In the simplest way, two similar samples are prepared for the respective microscopy modality and imaged independently. For a real correlation within the same sample, several options are possible: (1) In live imaging or *in vivo* imaging, the fluorescence signals from fluorescently-tagged proteins are recorded in the living specimen before the sample is prepared for electron microscopy for the purpose of either pure morphology or immunoelectron microscopy. The object that was imaged before by light microscopy is then re-localized and analyzed in the TEM. (2) During sample preparation, for example, in the dehydration step by freeze-substitution, fluorescent dyes can be included into the substitution cocktail to facilitate light microscopic observation prior to electron microscopy in order to identify the area of interest (Biel *et al.*, 2003). (3) A fluorescent probe can be used in the same specimen either on an adjacent section or on the same section by applying

on-section labeling. Here, the sample preparation has to fulfill the requirements of both, fluorescence- and electron microscopy (Karreman *et al.*, 2012). For visualization fluorescent- or gold-conjugated probes are applied (Schwarz and Humbel, 2007; Fabig *et al.*, 2012). A probe such as FluoronanogoldTM contains the fluorescent and electron-dense marker on the same antibody molecule (Takizawa and Robinson, 2000).

All these techniques either help finding the relevant spot in a large sample or choosing the right time point in a dynamic process. Depending on the question under investigation, a suitable workflow for correlative light- and electron microscopy needs to be worked out. For further reading Schwarz and Humbel (2009) and the books *Methods in Cell Biology*, volume 111, 2012 and volume 117, 2014 are recommended.

Immunogold Label Quantification and Labeling Specificity

Every experiment, also electron microscopic studies often regarded as 'descriptive,' has to provide quantitative data. A whole range of quantitative tools has been developed for the analysis of thin sectioned biological samples to provide so-called stereological estimations on number and size of structures. These take into account that a normal field of view in the TEM represents only a tiny fraction of the section, which in turn is only a tiny portion of the block, which is again derived from a much larger specimen or organ. The starting point of any quantitative immunoelectron microscopic study is therefore the correct sampling procedure. This means that for a faithful representation of the 'real' situation in the whole specimen, every part of it should have the same chance of being included in the final analyzed image. A tool called systematic uniform random sampling (SURS) applies a regular sampling array and makes sure that the sampling procedure is performed completely unbiased and efficient throughout the whole sampling cascade starting from the animal or cell culture dish, continuing with the selection of blocks and sections down to the level of the field of view in the TEM (Lucocq, 2012). SURS means that samples are selected in a regular systematic way by applying a pattern such as every third culture, block, and section. In the TEM analysis the selection of the starting point occurs at random (e.g., the upper left corner of the TEM-grid mesh), but the positioning of the successive fields of view is then made following a preset systematic pattern.

On randomly sampled fields of view colloidal gold labeling is easily quantified by its particulate nature. Label distribution can be assessed quickly by counting gold particles on organelles while scanning continuously in equally spaced parallel sweeps across the TEM-grid mesh. This label distribution can then be expressed in raw frequency data or as percentage of total number of gold. Often counting of 100–200 particles over 10–15 different compartments reveals a reproducible label distribution (Lucocq *et al.*, 2004). Gold counting in combination with stereological estimations of compartment area and membrane length provides readouts of the label concentration and density. Here profiles of cells or organelles on a TEM picture are overlaid with simple geometrical probes (arrays of test points, lines, rectangles) and encounters of these with structures of interest are counted. This could be points falling into an organelle profile area or

membrane-line intersections. Final values can be expressed as gold per μm^2 or per μm membrane length. Methods for statistical evaluation of gold counting allow determining whether organelles are preferentially or randomly labeled and whether the labeling differs between experimental groups. These employ simultaneous test point counting to create a random distribution. The observed labeling distribution can then be related to the 'expected' random distribution and evaluated by χ^2 statistics (Mayhew, 2005; Lucocq, 2008; Rabouille, 1999).

After having started with sample preparation and ending here with label quantification, lastly one important aspect has to be mentioned: the whole analysis comes down to the quality of the labeling probes, mostly antibodies. In immunoelectron microscopy we completely depend and rely on these tools. How can we be sure that the labeling is specific? Every researcher who has done immunocytochemistry has probably experienced that antibodies are very unreliable and variable tools. This is based on the nature of antibody structure and the biology of immunization. Therefore, specificity of the labeling needs to be proven. A recent review by Griffiths and Lucocq (2014) addresses this important question and is recommended for further reading. In brief, we summarize here several of their criteria which could be applied.

First of all, several antibody concentrations have to be applied. In the best case the labeling distribution is then evaluated by statistics to reveal whether it is random or preferential labeling. The labeling pattern should be in accordance with the published data about the expected localization of the antigen, so labeling of a plasma membrane protein should not be found in mitochondria, nucleus, or cytosol. It is also reassuring to have different antibodies recognizing different peptides from the same protein and giving the same result, although they could also possess the same cross-reactivity. Western blot data often show more than one band, but even a single clean band is no guarantee that the antibody will work specifically in immunoelectron microscopy, because epitopes treated with SDS for Western blots may differ significantly from aldehyde-fixed epitopes for immunocytochemistry. Another aspect is that epitopes on proteins can change during intracellular transport by posttranslational modifications which could affect the antibody–antigen interaction. Moreover, antibodies are able to cross-react with completely unrelated proteins. Knock-out (KO) controls of the protein of interest are helpful if they are available. So, if the antibody recognizes an epitope on a protein different from the target protein, the KO control will also be positive. But the KO control is not always conclusive: for example, under KO conditions related proteins might be up-regulated which could be detected by antibody cross-reaction. Related to the KO control, overexpression of the protein should increase the labeling. This control should be taken with caution, because artificial expression or overexpression can result in mis-localization of the protein and may induce changes of organelle structure. If functional antibodies are not available, often the protein is expressed as tagged version carrying hemagglutinin- (HA), myc- or, GFP-tags. Then tag-targeted antibodies are applied. But unfortunately these tags can change the property of the protein especially when the tag is rather large such as green fluorescent protein (GFP). If a pre-immune serum is available, this can be used to detect pre-existing immunity of the host due to infections. This is relevant for studies on infective pathogens. But in general, the

pre-immune serum is not indicative of the specificity of the antibody generated in the same host later. As another control, pre-absorption of the immunizing peptide should abolish the specific labeling. But this could also remove the cross-reactivity. In addition, the affinity of the antibody to the protein could be higher than to the peptide, so this cannot be detected by pre-absorption. Moreover, storage conditions have an impact on antibody properties. They could lose binding activity due to proteolysis, denaturation and aggregation. One should take care to optimize storage conditions as recommended by Griffiths and Lucocq (2014).

Thus, evaluation of antibody specificity requires a full set of controls, for example: KO control, application of several antibodies raised against different peptides of the same target protein, Western blot data with controls, pre-immune serum testing. Supporting data from independent experiments such as proteome analysis are highly valuable. A very good example of an elaborate evaluation of the specificity of immunolabeling can be found in Limbach *et al.* (2011) including the supplementary information.

Conclusions

- Depending on the question under investigation at the beginning of the experiment decisions have to be made regarding the sample preparation and labeling strategy.
- Samples can be fixed chemically with formaldehyde and low concentrations of glutaraldehyde or cryopreparation methods can be applied: cryo-immobilization by HPF and freeze-substitution.
- Immunolabeling can be performed on whole samples in preembedding labeling and whole mount labeling. Related to this, freeze-fracture immunolabeling is performed of replicas.
- On-section labeling is possible on samples after chemical fixation as well as cryopreparation. Embedding in resin suitable for immunolabeling or cryosectioning according to Tokuyasu can be applied. Cryosections are resin-free, so dehydration with organic solvents is omitted. But the lack of resin makes cryosections fragile.
- For the localization of rare events and for studies of dynamic processes methods for CLEM are available.
- Quantification of gold labeling is feasible by application of SURS and stereological tools for size and number estimations. Methods for statistical evaluation are available.
- Specificity of antibodies is a problem and needs to be demonstrated. Several criteria have to be applied, none of them alone is sufficient.

Imaging Cellular Architecture with 3D SEM

Introduction

Three-dimensional (3D) scanning electron microscopy (SEM) techniques provide information about the ultrastructure of cells and tissues, helping bridge the gap between light microscopy and transmission electron microscopy (TEM). Light microscopic techniques are typically limited in resolution to a few hundred nanometers, while TEM of resin-embedded fixed sections provides a resolution that can be 1–2 orders of magnitude higher, but is essentially limited to two dimensions (2D). To obtain information in the third dimension, a series of consecutive sections can be generated with an ultramicrotome, imaged, and then reconstructed into a 3D volume. Serial sectioning has been used effectively in some instances (Duman *et al.*, 2002; Marsh *et al.*, 1986; Sato *et al.*, 1999). Nevertheless, this approach is subject to limitations from missed sections, as well as artifacts arising from tears and folds in the thin sections imaged by TEM. There are well-established methods to obtain 3D structural information by combining TEM with electron tomography, but this is generally limited to sections that are <250 nm thick. Classical SEM methodologies enable visualization of the surface topology of whole objects, but do not provide 3D information about the internal features of the objects. This limitation can be overcome by combining SEM imaging with the use of a microtome or a focused ion beam (FIB) to progressively remove material from the surface of the imaged object. After each section step, a new surface is revealed; by stacking images generated from these newly created surfaces, it is thus possible to visualize the 3D density distribution in the imaged object. These new 3D SEM methods, which have been developed over the last decade, provide unprecedented tools for imaging cellular structure at nanoscale resolution.

A number of excellent articles have recently been published covering a number of aspects of 3D and serial section SEM imaging (Hughes *et al.*, 2014; Kizilyaprak *et al.*, 2014; Kuwajima *et al.*, 2013; Peddie and Collinson, 2014; Schauflinger *et al.*, 2013; Villinger *et al.*, 2014). In this article, our primary focus is on serial block face SEM (SBF-SEM) and FIB-SEM technologies, with a brief discussion of developments on the horizon of this emerging field.

Sample Preparation for 3D SEM

3D SEM requires that biological samples display a number of specific physical characteristics; these properties are dependent on the physics and mechanics of SEM backscattered imaging, the imaging modality most commonly employed for these technologies.

The first step in preparation of samples for most 3D SEM analyses requires fixation of the biological sample (using either chemical fixation or ultra-rapid freezing methods) (McDonald and Morphew, 1993; McDonald and Webb, 2011), followed by heavy metal staining, dehydration, and

resin embedding, similar in many respects to sample preparation for TEM imaging. This differs from sample preparation for topological SEM, which requires critical point drying and coating post dehydration, rather than embedding (Bray *et al.*, 1993). Although 3D SEM can be performed on samples without resin embedding (Heymann *et al.*, 2006), most delicate cellular ultrastructure is better supported, and there are fewer imaging artifacts, when the sample is resin-embedded (Drobne, 2013).

Because 3D SEM requires iterative imaging with the electron beam, it is important that samples be prepared in such a way that electrons are properly grounded. If the electrons are insufficiently grounded, a build up of negative charge (otherwise known as charging) repels the electron beam and produces imaging artifacts, degrading the quality of the image. Because the samples are resin-embedded (and thus electrically insulated), heavy metal treatment not only yields strong image contrast, but also increases the conductivity of the specimen, thereby reducing charging artifacts.

Orientation and Location of Region of Interest

3D SEM allows for imaging at higher spatial resolution than classical light and confocal microscopy. However, because the resolution is much higher, the fields of view are much smaller than that obtained using light microscopy. Thus, localization of the 3D volume or object of interest within the resin-embedded block of biological material is critical for effective imaging.

One method for locating an area of interest involves taking survey sections of the object within the resin-embedded block with an ultramicrotome (0.5–1 μm). These sections are stained with a histological stain such as Toluidine blue (Hayat, 2000), and correlated with the block so that one may locate the area of interest by SEM.

More recently, several groups have correlated 2D or 3D light microscopy with 3D SEM, allowing the localization of tagged elements within the architecture of the cell. In the study of adherent cells (Murphy *et al.*, 2011; Narayan *et al.*, 2014; Spiegelhalter *et al.*, 2010), cells expressing proteins tagged with fluorescent markers were grown on (or attached to) a marked surface, such as an etched, gridded coverslip. In the methods used for the studies listed above, confocal or standard fluorescent light microscopy is used to identify regions of interest or localize tagged proteins to specific areas of the cell; after light imaging, the samples are fixed, stained, and resin-embedded. The gridded coverslip is then removed, leaving a raised grid pattern on the face of the resin block. This pattern is then used to locate the region of interest on the prepared sample, and to later correlate the two sets of information.

While correlative light microscopy/electron microscopy allows one to generally localize tagged components to 3D SEM data, the recent development of clonable tags that can create electron dense markers offers a unique mechanism to directly image these elements by 3D SEM. APEX (Martell *et al.*, 2012)

and MiniSOG (Shu *et al.*, 2011) are both tags that are fluorescent in samples prior to resin embedding, but become electron dense after heavy metal staining, so that they may be directly observed both by light and electron microscopy.

3D SEM Techniques

A number of different methodologies have been developed for 3D SEM. Primarily, these techniques differ in the way that layers of material are removed (by abrasion or sectioning) and whether the newly exposed block face or the section itself is imaged.

One imaging approach commonly used for tissue imaging is SBF-SEM (Denk and Horstmann, 2004; Hughes *et al.*, 2014; 2013; Motskin *et al.*, 2011). This approach to imaging is commercially available from Gatan, Inc. as the '3View' system, which is a serial sectioning stage used in conjunction with an SEM microscope that collects backscattered electrons. The 3View system is designed with a diamond knife that is used to remove thin sections from the top of the block face, revealing a new face below after each cycle of operation (Figure 1(a)). The top of the block is imaged with SEM, followed sequentially with the removal of a new slice. SBF-SEM most commonly allows for a best x - y resolution of about 5 nm, and a z resolution (slice thickness) of 30 nm, provided that the sample has

Figure 1 Methods for 3D scanning electron microscopy (SEM) that image the block face. (a) In serial block face SEM (SBF-SEM), a resin-embedded block of cells or tissue is sectioned with a diamond blade inside the SEM stage. The top face of the block is then serially imaged with a scanning electron beam, and backscattered electrons are detected to produce an image. (b) In focused ion beam SEM (FIB-SEM), the 'slices' are abraded with a focused ion beam, typically gallium, and imaged with the electron beam. Imaging is done orthogonally to the top of the block. (c) In preparation for FIB-SEM imaging, the FIB is used to mill a trench in front of the collection area. A pad of carbon and platinum, marked with a pattern for tracking z -spacing of slices, is deposited at the top of the block at the area of data collection.

been prepared optimally for this technique. This tool is especially useful for studying large sample areas (up to $\sim 800\ \mu\text{m}$ in x and y directions), limited primarily in the x - y plane by the size of the diamond knife. SBF-SEM instruments can acquire datasets with potentially thousands of sections (up to $600\ \mu\text{m}$ in the z plane) per imaging session.

In SBF imaging, the build up of charge during the data collection process can lower the quality of the images. One way to address this problem is to integrate a metal coating device into the SEM chamber, as reported by [Titze and Denk \(2013\)](#). Currently, however, the best ways to help dissipate charge and create stable imaging conditions are by coating the sides of the sample with metal, and by infusing additional heavy metals throughout the sample. This addition of metal stains also increases the number of backscattered electrons generated from the sample, thereby increasing the signal. Additionally, traditional epoxy resins may be too soft for SBF-SEM; the use of a harder resin, such as Durcupan ([Deerincx et al., 2010](#)), can be helpful in sample preparation protocols for SBF-SEM, especially when anticipating the need for better z resolution (i.e., thinner slices).

The most common use for SBF-SEM is for the analysis of large volumes. Some examples of these include imaging and following long processes in the central nervous system, and tracking of retinal neurons or long collagen fibrils ([Briggman et al., 2011](#); [Starborg et al., 2013](#); [Wilke et al., 2013](#)). In addition, some studies have also used SBF-SEM for statistical analyses where many cells or bacteria were required, as this method allows for very large datasets ([Hughes et al., 2013](#)).

An alternative approach for 3D SEM imaging is FIB-SEM (also referred to as ion abrasion (IA)-SEM) ([Giannuzzi and Stevie, 2005](#); [Subramaniam, 2005](#)). The instruments used for this method have two beams: a scanning electron beam for imaging the sample and an ion beam that abrades material from the exposed surface of the specimen ([Figure 1\(b\)](#)). While gallium is the material used most commonly in these instruments, other sources such as iridium or elemental gold are also used occasionally.

Because the current in the FIB can be controlled precisely within the pico-ampere range, it is possible to obtain significantly higher z resolution with the FIB-SEM as opposed to the SBF-SEM system. In addition, the closer placement of the sample surface to the pole piece of the electron beam gun (shorter working distance) in the FIB-SEM also allows a higher x - y pixel resolution. Thus, images can be recorded with $3\ \text{nm}$ pixel resolution in the x - y plane and $3\ \text{nm}$ z -slices, generating 3D volumes at significantly higher resolution than possible with SBF-SEM.

The use of two beams in FIB-SEM instruments and the mechanism by which the FIB operates require that the sample stage be tilted, so that both beams act on the sample at the same location. Once the object of interest is located, the stage is tilted ($\sim 54^\circ$ in presently available instruments) and the beams are aligned to be incident at the same region of the specimen. The FIB is oriented directly above the block face, and a pad of carbon and platinum is deposited on top of the imaging area ([Figure 1\(c\)](#)). This pad helps neutralize charging at the sample imaging area, reducing the need for the extra treatment of heavy metals that is required for SBF-SEM. This pad can also provide a platform for a pattern of marks that can

be used to keep track of the thickness of the ablation along the z axis, a process known as z -tracking ([Boergens and Denk, 2013](#); [Narayan et al., 2014](#)). The pad also protects the top of the imaging area from being damaged.

After the protective pad is deposited, a 'trench' ([Figure 1\(c\)](#)) is milled using the FIB, which exposes the imaging area. Whereas the top face of the block is imaged in SBF-SEM, the sample face to be imaged by the electron beam in FIB-SEM is orthogonal to the top face of the block ([Figure 1\(c\)](#)); this must be taken into account when orienting and trimming the sample prior to data collection, as the successive slices removed are from the interior, not the surface of the block.

Typically, FIB-SEM imaging is done on areas that are smaller than that accessible with SBF-SEM. With present-day technology, collection areas with dimensions of $\leq 50\ \mu\text{m}$ in the x direction and $\leq 30\ \mu\text{m}$ in the y direction can be achieved. This limitation derives mainly from the geometry of the imaging as noted above. FIB-SEM technology has been used to collect high-resolution 3D data, on cells and tissues, primarily for smaller volumes at higher resolution. Early FIB-SEM imaging focused on imaging of whole cells and subcellular structures, along with correlation with light microscopy ([Heymann et al., 2006](#); [Murphy et al., 2011](#)). However, several examples of tissue imaging using FIB-SEM have been reported, including 3D imaging of carbon nanotubes in lung tissue ([Kobler et al., 2014](#)), as well as tissues such as cardiac muscle ([Lafontant et al., 2013](#)), skeletal muscle ([Dahl et al., 2015](#)), bone ([Schneider et al., 2011](#)), and brain ([Blazquez-Llorca et al., 2013](#); [Bushby et al., 2011](#)). In tissues such as these and the duodenal epithelium shown in this article, where cellular function is spatially organized within a cell, FIB-SEM can be especially useful for studying the intricate interactions of cellular membranes and organelles.

The higher resolution of FIB-SEM makes it especially suitable for imaging 3D virus distribution in infected cells, as typified in studies of virological synapses formed between various cell types involved in HIV transmission ([Felts et al., 2010](#); [Bennett et al., 2009](#); [Do et al., 2014](#); [Nikolic et al., 2011](#)). Individual HIV cores within mammalian cells, which are $< 40\ \text{nm}$ across, can also be clearly visualized with FIB-SEM ([Narayan et al., 2014](#)), but would be challenging to resolve in 3D with SBF-SEM, even with sections as thin as 20 – $30\ \text{nm}$.

As with any imaging technique, artifacts and defects can be a problem for data acquired by either SBF-SEM or FIB-SEM. SBF-SEM is particularly prone to imaging artifacts caused by charging. FIB-SEM requires a very smooth top block face, as irregularities on the surface at the top of the imaging plane can introduce 'curtaining' defects (vertical marks that resemble a curtain through the volume). The FIB-SEM instrument is particularly useful for working with samples with uneven hardness that are difficult to section, such as bone, or materials that include silicate or carbonate along with biological material ([Reznikov et al., 2013](#); [Hildebrand et al., 2009](#)). In general, SBF-SEM is most useful for the collection of large volumes that need not be imaged at high resolution, while FIB-SEM is better suited to smaller volumes that are to be imaged at higher, isotropic resolution.

A few other specialized methodologies for 3D SEM have also been developed recently, although these tend to have more specific biological applications. One example is a technique developed primarily for imaging neural tissue, where the

sections (rather than the block face) are imaged by SEM. Fixed, stained, and resin-embedded biological material is sectioned with an ultramicrotome, and hundreds of 50–100 nm sections are collected on slides or silicon substrates, and then post-stained again for imaging in the SEM (Horstmann *et al.*, 2012; Kuwajima *et al.*, 2013). Another similar technique is array tomography, where the collected serial sections are first imaged with light microscopy, before being treated with heavy metal stains for SEM. This technique provides correlative 3D immunofluorescence imaging with SEM imaging. In the methodologies where the sections are imaged, the sections may be stored and re-imaged, or in some cases, serially labeled with several different probes (Micheva and Smith, 2007; Oberti *et al.*, 2011; Wacker and Schroeder, 2013).

Data Handling and Segmentation

Despite their differences, both SBF-SEM and FIB-SEM methods produce stacks of 2D images, which then must be aligned into a 3D volume and analyzed (Figure 2). Many algorithms are available that can correct for stage movement and beam instability to produce an aligned stack of images; these alignment procedures can be done with programs such as IMOD (Kremer *et al.*, 1996). In addition, although it is possible to acquire data with fully isotropic voxels, it is more common to have higher resolution in either the x - y or z directions, and these differences can be easily accommodated in preparation of the final aligned stack and in subsequent segmentation steps.

3D SEM methods are an especially powerful tool for visualizing the architecture and connectivity of intracellular organelles. An example of FIB-SEM imaging of murine duodenum epithelium is shown in Figure 2, revealing cellular components with the type of contrast usually observed for thin section imaging with TEM. Thus, within the cell, one can clearly see large branching mitochondria and neighboring endoplasmic reticulum studded with ribosomes. The interface between two epithelial cells can be seen, with desmosomes visible at the basolateral membrane interface. Microvilli can also be seen at the apical surface, with actin bundles extending down into cytoplasm of the cell.

After alignment, segmentation of the individual cellular components is required to analyze the 3D nature of the organelles or features of interest. Segmentation can sometimes be done automatically, using volume rendering tools supported in freely available packages such as IMOD (Kremer *et al.*, 1996), Slicer 3D (Fedorov *et al.*, 2012), ImageJ (Schneider *et al.*, 2012), or UCSF Chimera (Pettersen *et al.*, 2004), or in commercially available packages such as Avizo (Visualization Sciences Group, FEI). Automated tools for segmentation are particularly useful when there are significant differences in contrast between the object of interest and the surrounding morphology (e.g., see Figure 2(b)).

For analysis of more complex intracellular components, segmentation is frequently done manually, by tracing the object of interest on each image throughout the volume, in the xy plane, the xz plane, and the yz plane, to ensure continuity of the object in all directions. Although manual segmentation is

Figure 2 2D scanning electron microscopic (SEM) images are aligned into a 3D volume. (a) 2D FIB-SEM image of duodenum epithelia, showing the brush border and the basolateral cell boundary of two epithelial cells. (b) Individual 2D 'sections' from FIB-SEM imaging correspond to different z -thicknesses in the original tissue. These are computationally aligned and volume rendered. All gray scale images have been contrast inverted to aid interpretation.

time-consuming, it is often necessary when the contrast differences are low, or if the continuity of the object changes within the thickness of a section. One can also use customized procedures to bridge the gap between fully automated and fully manual segmentation; scripts can inform a program such as Slicer 3D (Fedorov *et al.*, 2012) to preferentially select objects of a certain shape or size. This is particularly useful when many similar objects within a cell, like regularly shaped virions or vesicles, need to be segmented and analyzed (Murphy *et al.*, 2011).

Manual segmentation of the duodenal image stack reveals the juxtaposed basolateral surfaces of both cells and the extensive winding and folding of the two membranes (Figures 3(a)

and 3(b)). Individual mitochondria were also segmented manually from this volume. Unexpectedly, 3D segmentation revealed that what appeared to be one large mitochondrion

Figure 3 Segmentation of a 3D volume can illuminate the 3D architecture of individual subcellular components. (a) 2D SEM showing the basolateral surfaces between two epithelial cells. (b) 3D segmentation reveals complex folding of the two juxtaposed membranes. (c) 2D SEM image showing a mitochondrion with visible cristae. (d) 3D segmentation reveals the highly branched structure of this single mitochondrion. (e) 2D SEM image showing mitochondrion with neighboring rough endoplasmic reticulum. (f) 3D segmentation reveals lacy rough endoplasmic reticulum wrapping around the mitochondrion. Gray scale images have been contrast inverted to aid interpretation.

and other, small, oblong mitochondria in the 2D sections (Figure 2(a)) were in fact all part of one large mitochondrion with multiple branches (Figures 3(c) and 3(d)). Segmentation of the rough endoplasmic reticulum reveals the structure of fenestrated membranous network that blankets a lobe of mitochondrion, and the image resolution is adequate to visualize individual ribosomes that decorate the membrane (Figures 3(e) and 3(f)).

One of the key reasons to use 3D SEM techniques is that they directly reveal the 3D architecture of organelles and proximity to other objects within a volume. Illustrating these objects and drawing conclusions from the data is thus highly dependent on segmentation and analysis of the data volumes. Choosing whether to segment manually or automatically – or whether to write and use customized scripts to segment and analyze particular aspects of the data – depends on the type of question being investigated and the nature of the data. Provided there is sufficient contrast, a simple volume rendering can suffice for some projects; for precise measurements of objects in just one or two samples, manual segmentation is usually best. However, for statistical analysis of many similar objects from a number of samples, customized scripts can provide higher objectivity and reproducibility. As this technique becomes more common, such scripts may become available for use in open access software such as Slicer 3D (Fedorov *et al.*, 2012).

New Methods and Future Developments

One classic problem in imaging is the trade-off between resolution and data acquisition time. With SEM imaging in particular, a long image acquisition time can lead to imaging artifacts from the build up of charge. One unique advantage of SEM imaging is that it is possible to limit the regions of the block surface that are imaged to only those that are of interest, rather than imaging the entire surface. A recently developed method, ‘keyframe imaging,’ is a promising approach to achieve this type of control in imaging (Narayan *et al.*, 2014). In this approach, one can select specific regions of interest within a 3D volume, and image these at the desired resolution in x , y , and z . This can be combined with recording keyframe images of the entire surface every 30 or 40 slices to obtain a global view of the cell at lower resolution, which can often be of sufficient quality to provide spatial context for the local higher resolution images. This feature was recently developed in the Fibics Inc. software package Atlas3D, which runs the automated data collection process integrated into the Zeiss FIB-SEM instruments. The ‘key-frame’ feature not only allows for a lower resolution overview of the entire imaging area, but also allows the user to dynamically adjust the position of the region of interest during the run. A similar feature is also available for SBF-SEM imaging.

Another important recent technical advance for FIB-SEM imaging is the introduction of z -slice tracking (Narayan *et al.*, 2014). A carbon and platinum pad is deposited on the top face of the resin block, with a defined pattern of lines etched into the pad. As the data run progresses, the distance between the marks changes, and these distances can be used to define the precise z of the image being taken. The feature also allows for a significantly higher level of automation in setup and FIB stability monitoring, as well as automatic stigmation of the electron

beam. These focus-tracking solutions are not yet available for SBF-SEM. In both SBF-SEM and FIB-SEM approaches, the resolutions achievable by SEM do not yet match what can be obtained by TEM, but new detector developments may help to close this gap, and better techniques for reducing sample charging and imaging artifacts and for increasing run stability will likely lead to better quality data. And as 3D SEM becomes more widely used, more publicly available tools and scripts will likely be developed for automated analysis of cells and tissues.

Another area where advances are beginning to be made is in the use of unstained samples for FIB-SEM, where the imaging is carried out with frozen specimens maintained at temperatures below -150°C . When cells and tissues are frozen rapidly and kept below this temperature to prevent ice crystal formation, the cellular components are in a near-native state. This strategy has been difficult to implement mainly because of the absence of contrast-generating stains. In addition, there are difficulties applying a conductive coating to the frozen sample, but progress is being made (Huang *et al.*, 1994; Hayles *et al.*, 2007; Schertel *et al.*, 2013). Future developments that overcome these contrast limitations may enable cryo FIB-SEM to become a more commonly used method for 3D cellular imaging.

In summary, 3D SEM approaches provide unique access to cellular morphology at resolutions 1–2 orders of magnitude higher than that possible with confocal microscopy. Techniques that fall under this umbrella can deliver quantifiable information on the size, shape, and distribution of cellular components and organelles at nanometer resolution, without the need for specific tags, in a highly automated, reproducible, and unbiased procedure. With the new developments in correlative imaging and EM-compatible clonable tags, as well as the use of probes for array tomography, 3D SEM is poised to allow researchers to combine the best aspects of light and electron microscopy in 3D. For biological samples where this type of 3D information is necessary, 3D SEM thus bridges the gap between classical light and EM methodologies, and offers a unique glimpse of 3D cellular and tissue architecture.

Introduction – Fluorescent Proteins

To coordinate and control the myriad molecular interactions that create life, cells exhibit a remarkable 3D organization. For example, DNA combines with proteins to create neatly packed chromosomes; lipids and proteins combine to form networks of membranes and organelles; and polymeric scaffold proteins crisscross the cell to form the exquisite yet robust cytoskeleton. Therefore, a crucial technique for understanding cell biology has always been the ability to image this intricate cellular architecture. Because so much of this structure is built over the cellular length scale of microns, the light microscope, with its submicron resolution, has always been the best friend of the cell biologist. Indeed, it is no accident that the field of cell biology was born out of the invention of this instrument.

The resolution limit for light microscopy, governed by Abbe's law, is roughly half the wavelength of light used – approximately 0.2 μm for blue light. Nevertheless, most cellular architecture larger than this remains invisible to the microscopist because the molecular assemblies that form it interact weakly with light; the cellular milieu therefore lacks contrast and appears largely amorphous after simple magnification. It is for this reason that staining techniques – the interaction of some light-absorbing substance with specific elements of the cell – are vital to generate contrast for specific architectural elements. In contemporary cell biology, fluorescence staining has become the dominant method, for two principal reasons: firstly, fluorescent probes can be easily and specifically targeted to individual molecular species; and secondly, the labeled

species emit a particular color of light that can be filtered out from all others. The resulting images are unparalleled in their contrast and, with modern confocal microscopy, the resolution attained is as high as Abbe's limit will permit.

Stunning as such fluorescence micrographs of cellular architecture are, they can nonetheless only tell part of the story: chromosomes are in a continuous state of flux, membranes restlessly fuse and bud off from each other, and the cytoskeleton constantly grows and shrinks to keep cells sturdy yet pliable. This incredible dynamism is fundamental to the business of life at the cellular level. For this reason, cell biologists need to be able to watch the living cell as its components move and interact, and fluorescent stains that can be applied to the living cell without perturbing these molecular components are essential tools.

For many years, the availability of such vital fluorescent dyes was limited to the imaging of dynamic cellular processes. However, all that changed with the discovery of the biochemical process that allowed the crystal jelly, *Aequorea victoria*, to generate its ethereal green luminescence. The crucial breakthrough came from the discovery, by Osamu Shimomura and colleagues, that the blue light emitted by the jellyfish's aequorin protein was converted to green by the eponymous green fluorescent protein, or GFP (Morise *et al.*, 1974). After the GFP gene was cloned, Martin Chalfie and colleagues realized that using molecular genetics, this gene could be introduced into cells from any organism. Not only would that cause the cells to fluoresce green, but through fusion of the GFP gene with others, individual fluorescent proteins could be made to

Figure 1 Imaging with multiple fluorescent proteins. A HEK-293 cell expressing enhanced green fluorescent protein (eGFP)-tagged plasma membrane protein (the prenylated polybasic peptide from K-Ras), monomeric cherry fluorescent protein (mCherry)-tagged Golgi protein (the transmembrane tail from Giantin), cyan fluorescent protein (CFP)-tagged ER marker (the transmembrane domains from Sacm11), and the infrared fluorescent protein (iRFP)-tagged mitochondrial resident protein (the mitochondrial targeting peptide sequence from AKAP1). Scale bar=10 μ m.

exhibit this fluorescence, lighting up specific cellular structures (Chalfie *et al.*, 1994). The uniquely compacted, independent folding of GFP, its lack of requirement for cofactors to exhibit fluorescence, and tireless optimization of the gene sequence to improve the efficiency of its production, stability, and brightness by Roger Tsien and others (Heim *et al.*, 1995; Zhang *et al.*, 1996), has yielded one of the most powerful tools in modern cell biology. GFP technology allows cell biologists to introduce fluorescent labeling in living cells to virtually any protein or structure of interest, and to observe this fluorescence in living cells and organisms. It thus represents the marriage of two revolutionary technologies: the historic, physical science of optics with the more recent molecular genetics. This journey from a relatively obscure jellyfish species to a technical tour-de-force in modern biomedicine is also a resounding endorsement of the power of curiosity-driven research in creating serendipitous discoveries and revolutionary new technologies. For bringing GFP to the scientific community, Shimomura, Chalfie, and Tsien were awarded the 2008 Nobel Prize in chemistry.

In the decades since the discovery of GFP, the field of genetically encoded fluorescent probes has exploded. Along with the aforementioned optimization of GFP itself, spectral mutants exhibiting, for example, cyan (CFP) and yellow (YFP) fluorescence have been devised (Heim and Tsien, 1996). Yet more organisms with fluorescent proteins have been discovered, such as the *Discoma* coral with its red fluorescent protein DsRed (Matz *et al.*, 1999), since carefully optimized to produce commonly used bright, stable orange, and red variants that are widely used today, such as mCherry (Shaner *et al.*, 2004). The recent utilization of bacterial phytochrome receptors for the generation of near infrared fluorescent proteins (Shcherbakova and Verkhusha, 2013) completes the visible spectrum of fluorescent proteins and extends it into the invisible infrared region. This makes it possible to introduce several different colored fluorescent proteins and thus to image multiple proteins and structures simultaneously in the same living cell (Figure 1).

The usefulness of fluorescent proteins has been even further extended by the discovery of proteins or mutants in which

fluorescence can be in some way actively controlled. First amongst these was the production of photoactivatable fluorescent proteins (PA-FP) such as PA-GFP, which proceeds from a nonfluorescent to the normal green fluorescent state after illumination with ultraviolet (UV) light (Patterson and Lippincott-Schwartz, 2002). In a similar vein, other proteins have been described that yield changes in fluorescence in response to UV light, for example, from green to red in the case of Eos (Wiedenmann *et al.*, 2004) and its optimized derivatives (McKinney *et al.*, 2009). These photoconvertible fluorescent proteins (PC-FPs) yield additional advantages for studying the dynamics of fluorescently labeled molecules, as we will see in following sections. Note that these fluorescent proteins and their derivatives are continually being discovered and optimized by researchers across the globe; the reader is encouraged to look for recent review articles describing the most up-to-date versions. Excellent recent overviews are listed here (Kremers *et al.*, 2011; Miyawaki, 2011).

Fluorescent Proteins as Probes for Function

As well as revealing the dynamic structural organization of proteins inside living cells, fluorescent proteins have also been adapted in many ingenious ways to enable probing of the dynamics and interactions of the protein molecules themselves. Perhaps the first illustration of this was fluorescence recovery after photobleaching (FRAP); with this method, fluorescent molecules in a defined subregion of the cell are photobleached with intense light (Axelrod *et al.*, 1976). Motion of the now nonfluorescing bleached molecules, combined with their replacement by unbleached fluorescent molecules, causes recovery of fluorescence into this bleached region (Figure 2). By following this process in real time in living cells, the observed kinetics can yield information about the physicochemical processes at work – such as the diffusion coefficient of the protein, or the off-rate of a binding reaction with an immobile partner. Information such as this can yield important insights into how a protein is able to function in its biochemical setting, such as defining the range over which

Figure 2 Fluorescence recovery after photobleaching (FRAP). A HEK-293 cell expressing eGFP-tagged plasma membrane protein (the myristoylated and palmitoylated peptide sequence from Lyn kinase) is observed with confocal microscopy. A small region of the membrane was photobleached at high laser power, and the recovery recorded by time-lapse imaging (see insets at bottom). The measured fluorescence intensity in this bleached region can be used to determine the kinetics of the recovery process and, in this case, determine an apparent lateral membrane diffusion coefficient of $\sim 0.9 \mu\text{m}^2 \text{s}^{-1}$. Scale bar = $10 \mu\text{m}$.

an activated protein can exert its biochemical effect (Teruel and Meyer, 2000), or the protein flux through a membrane compartment such as the Golgi apparatus (Patterson *et al.*, 2008). Similar experimental techniques now permit this process in reverse, through the use of PA-FPs or PC-FPs to selectively and acutely activate fluorescence of a sub-pool of fluorescent molecules, and then follow their redistribution in the cell. Although techniques such as these are not limited to fluorescent proteins – indeed, the first demonstrations used antibody-conjugated organic dyes (Axelrod *et al.*, 1976) – the same advantages of fluorescent proteins apply; that is, they can be used to tag virtually any protein of interest and used to study its dynamics.

Another powerful technique for assessing protein dynamics with fluorescent proteins is fluorescence correlation spectroscopy (FCS), wherein the fluctuation of fluorescence intensity in a specific illuminated region of the cell is measured (Bacia *et al.*, 2006). Since this fluctuation occurs due to the motion of fluorescent proteins into and out of the illuminated region, information on protein mobility can be extracted as for FRAP. However, FCS has the capacity to make measurements on a much faster timescale, and therefore to capture more dynamic events. The use of two different colored fluorescent molecules using fluorescence cross-correlation spectroscopy (FCCS) allows the investigation of their interactions (Bacia *et al.*, 2006).

In addition to the ability to image protein localization in living cells, molecular genetics makes it possible to engineer proteins in order to produce biosensors that can report on the presence and/or dynamics of other types of biologically active molecules. Prominent examples include the use of specific lipid-binding domains, fused to fluorescent proteins, to image the localization and dynamics of membrane lipids (Várnai and Balla, 1998; Meyer *et al.*, 1998). This approach has been particularly useful in the study of signaling lipids that are acutely synthesized or degraded in response to cellular stimulation.

GFP has also proved to be a robust scaffold for the generation of other types of biosensor. Mutagenesis of the wild-type GFP sequence led to the discovery of the so-called ‘pHluorins,’

Figure 3 Calcium-dependent fluorescence using GCaMP. In the absence of calcium (left), circularly permuted GFP (cpGFP) is weakly fluorescent due to quenching by water molecules, which in this configuration can access the normally buried chromophore. Upon calcium binding to calmodulin (CaM; right), a conformational change in CaM ‘wraps’ the M13 peptide. This prevents solvent access to the chromophore, and results in a calcium-dependent increase in fluorescence.

whose fluorescence is strongly dependent on pH (Miesenböck *et al.*, 1998). Not only are they a valuable tool for probing the chemical environment of the cell, but they can also be used as a biosensor for regulated exocytosis and synaptic transmission, when acidic vesicles fuse with the plasma membrane exposing them to the neutral extracellular milieu. A strikingly elegant approach to the engineering of GFP into a biosensor was the generation of GCaMP, a GFP whose fluorescence intensity depends on calcium ions, and is thus an indicator of cellular calcium concentration (Nakai *et al.*, 2001). GCaMP consists of an N-terminal ‘M13’ peptide, the circularly permuted GFP (i.e., the C-terminal half of the protein followed by a short linker to the N-terminal half) fused at the C-terminus to the calmodulin protein (Figure 3). In this configuration, the GFP fold forms but is weakly fluorescent due to solvent exposure of the normally buried GFP chromophore. However, binding of calcium

Figure 4 FRET. HEK-293 cells expressing cyan (CFP) or yellow (YFP)-conjugated pleckstrin homology (PH) domain proteins that bind to a membrane lipid, PIP_2 are examined with wide-field fluorescence microscopy. When bound to the lipid, the PH domains are concentrated on the membrane surface, leading to FRET between the CFP and YFP molecules, increasing the FRET ratio of YFP emitted relative to CFP when CFP is excited. However, after activation of a PIP_2 -cleaving enzyme, phospholipase C, the PH domain proteins are released from the membrane and become diluted, increasing the distance beyond the FRET range. Hence the FRET ratio YFP/CFP emission decreases. In this manner, FRET between the two probes acts as a sensitive biosensor for PIP_2 concentration.

by calmodulin causes it to wrap around the M13 peptide, 'plugging' the exposed chromophore (Figure 3) and dramatically increasing fluorescence (Akerboom *et al.*, 2009). Several iterations of GCaMP have since been produced, with dramatic increases in sensitivity. These enable calcium signaling to be monitored in whole cells and organisms with exquisite sensitivity, even allowing synaptic calcium signaling to be viewed *in vivo* (Chen *et al.*, 2013). Coupling of mutated GFPs to voltage-sensitive proteins has also formed the basis for voltage sensors (Siegel and Isacoff, 1997), which have recently been improved by the fusion of a voltage-sensing domain to a pHluorin (Jin *et al.*, 2012). Beyond the utilization of GFP variants, yet another sensitive voltage sensor has recently been engineered from an intrinsically voltage-sensitive and fluorescent archaeal rhodopsin (Kralj *et al.*, 2012). These voltage sensors now have the capacity to detect electrical activity associated with neuronal activity and show great promise for the study of circuit function in living brains.

A spectroscopic quirk of fluorescent molecules, including the fluorescent proteins, allows the nanometer-scale proximity of two such molecules to be probed via the phenomenon of Förster resonance energy transfer (FRET); this is the radiationless transfer of energy between two fluorescent molecules when the emission spectrum of one overlaps substantially with the absorption spectrum of the other (Stryer and Haugland, 1967). This energy transfer is highly dependent on molecular proximity and dipole orientation and can be monitored either

as a decrease and increase in the emission of the donor and acceptor fluorophore, respectively, (called sensitized emission, Figure 4) or as a change in the fluorescent lifetime of the donor (used in fluorescence lifetime imaging microscopy or FLIM (Sun *et al.*, 2012)). FRET between fluorescent proteins was first practically achieved with CFP and YFP (Miyawaki *et al.*, 1997), although FRET pairs have since been systematically improved and often utilize green and red fluorescent proteins (Lam *et al.*, 2012). As well as being a powerful probe for protein–protein interactions, FRET between two fluorescent proteins forms the basis of many biosensors. For example, in the case of lipid biosensors, the increased density of biosensors when bound to lipids in a membrane produces more FRET than with their more dilute unbound forms in the cytosol; hence, FRET efficiency correlates with lipid abundance (Figure 4). Alternatively, biosensors often take the form of a protein receptor whose conformation is shifted upon binding of a small molecule; this shift reorientates N- and C-terminally fused fluorescent proteins, moving them either into or out of FRET distance or orientation. Such tools are extremely useful in the monitoring of small messenger molecules produced during signal transduction, such as cyclic adenosine monophosphate (Ponsioen *et al.*, 2004) or inositol trisphosphate (Tanimura *et al.*, 2009). Coupling of a voltage-sensitive domain to two fluorescent proteins also forms the basis of 'Mermaid2,' a recently described sensitive FRET-based voltage sensor (Tsutsui *et al.*, 2013).

Imaging Cells in Whole Organisms

The cells that comprise complex organisms have a highly ordered 3D organization, forming tissues and organs. Furthermore, each cell interacts with many different cell types and responds to signals from these other cells, the surrounding extracellular environment, and the endocrine, nervous, and immune systems. Therefore, the ability to perform time-lapse imaging at the cellular and subcellular level in living organisms (intravital microscopy) is essential to understand complex processes such as vertebrate embryonic development, tumor metastasis, and brain plasticity. The fluorescent protein revolution, coupled with the development of microscopes capable of gentle deep tissue imaging, has made such ambitious goals a reality. Molecular genetic techniques enable both targeting of fluorescent proteins or biosensors to particular cell types, and temporal control of their expression. Imaging in whole organisms of course presents its own set of challenges; in particular, minimizing photo damage and achieving sufficient depth penetration in a highly light-scattering environment are key factors. In some more superficial tissues, specialized microscopes may not be required. For example, imaging superficial tumor cells (Pittet and Weissleder 2011) or tracking GFP-expressing metastatic cells relative to blood vessels is possible with a confocal microscope (Wyckoff *et al.*, 2000). But for deeper tissues, specialized microscopy techniques are required, and we will discuss the two major methods that have been developed and utilized for this purpose.

2-photon microscopy, as the name suggests, is based on the principle that a single molecule can absorb two photons of light near-simultaneously (Goeppert-Mayer, 1931); hence, a fluorophore can be excited by two lower-energy (longer wavelength) photons if they arrive in a sufficiently short-time window. Making use of newly developed high-powered lasers that could generate very rapid light pulses, Winfried Denk and colleagues built the first laser-scanning 2-photon microscope in 1990, demonstrating that 2-photon excitation of fluorescent dyes was possible in living cells (Denk *et al.*, 1990). 2-photon fluorescence microscopy provides major advantages for imaging in whole organisms. First, it uses infrared excitation, which can penetrate deeper, is less subject to scattering, and because of its lower energy, is less damaging to living cells. Second, fluorescence excitation is confined to a very small focal volume, which greatly reduces photobleaching and photodamage (see later), and generates an optical sectioning effect that permits 3D imaging. Hence, high resolution imaging deep within living tissue is now possible.

Long-term *in vivo* 2-photon imaging has found greatest utility in the mammalian brain (Figure 5). The first live animal 2-photon imaging study to use fluorescent proteins tracked tiny protrusions from neuronal dendrites over hours in the developing rat brain (Lendvai *et al.*, 2000). Even more exciting, the subsequent development of chronic imaging windows (Trachtenberg *et al.*, 2002; Grutzendler *et al.*, 2002) enabled similar longitudinal tracking of subcellular neuronal structures to be performed over weeks or even months even in the adult mouse brain. *In vivo* 2-photon microscopy has now become a widespread technique that enables changes in neuronal structure and function to be tracked during development,

Figure 5 2-photon imaging of GFP-expressing neurons in the living mouse brain. Image shows GFP-expressing inhibitory periglomerular neurons in the olfactory bulb of a young adult mouse imaged through a cranial window. Scale bar 10 μm .

plasticity, learning, and behavioral tasks, even in awake mice (Holtmaat and Svoboda, 2009). 2-photon imaging of neuronal structure and function has also been extended to *Drosophila* (Wang *et al.*, 2003), and even primates (Stettler *et al.*, 2006). Outside of the brain, 2-photon microscopy of fluorescent proteins and biosensors has found utility in the fields of cancer biology and immunology, for example, to monitor gene expression and track cells deep within tumors (Brown *et al.*, 2001), and in developmental biology (Hardin, 2006). The recent development of 2-photon microendoscopy further extends the depth penetration of this already powerful technique (Barretto and Schnitzer, 2012).

More recently, a second class of microscopes that are ideally suited to rapid whole organism imaging have been developed. Light sheet fluorescence microscopy (LSFM), also known as single-plane illumination microscopy (SPIM), uses a thin sheet of light to illuminate only the focal plane of the detection optics. This produces high signal:noise ratio images and as for 2-photon microscopy, by spatially restricting fluorescence excitation, photobleaching and phototoxicity are minimized. Fast data acquisition is then achieved by simultaneous detection of emitted light from the entire illuminated sheet using a sensitive camera, in some cases with subcellular resolution. LSFM permits very gentle live imaging, enabling many thousands of images of entire organisms to be collected over long periods of time.

The first application of LSFM was to image the rhodamine-stained guinea pig cochlea after using a chemical clearing agent to render the tissue transparent (Voie *et al.*, 1993). But once again it was GFP that really brought LSFM to the forefront, when Ernst Stelzer's laboratory showed that it enabled GFP-labeled muscles throughout a transparent fish embryo to be visualized (Huisken *et al.*, 2004). This opened the door to continuous imaging of embryogenesis over many hours or even days, providing unprecedented insight into this dynamic process in fish and insect embryos (Keller and Dodt, 2011). A

type of LSM termed objective-coupled planar illumination has also been used to simultaneously track GCaMP2 calcium signals from hundreds of neurons in the living mouse brain (Holekamp *et al.*, 2008).

Where dynamic information is not required, the use of clearing techniques also allows opaque tissues and organisms to be studied with LSM: structures deep in the mammalian brain, whole mouse embryos and even entire adult *Drosophila melanogaster* fruit flies can be visualized (Dodt *et al.*, 2007). Whatever the tissue or organism of interest, the ability to sweep the illumination sheet now permits generation of 3D data sets without moving the specimen (Keller *et al.*, 2008). LSM technology is advancing all the time, and the range of applications it can be used for grows concomitantly. We direct the reader to recent review articles for a more complete description of the state-of-the-art, but note that LSM can now be combined with 2-photon excitation and even super-resolution techniques (see below) (Keller and Dodt, 2011).

Breaking the Diffraction Barrier

Although it was long accepted as an immutable law of physics, Abbe did not have fluorescence in mind when deriving his law of limiting resolution. As such, even though the light emitted from a fluorescent source – such as a fluorescent protein – is subject to blurring into a diffraction-limited spot by the microscope optics (its so called point spread function), higher resolution information is attainable if we only know the location in which that molecule was excited (Hell, 2008). Several ingenious methods for achieving this goal have recently been invented, all of which lend themselves to imaging fluorescent probes inside cells.

The first broad method to achieve super-resolution is to reduce the effective region in which fluorescent molecules become excited. Saturated structured illumination microscopy (SSIM) uses patterned illumination to limit the excitation pattern of the fluorescent molecules in the sample, leading to a doubling of the resulting resolution, and often revealing key structural features that are normally hidden just beneath Abbe's limit (Schermerle *et al.*, 2008; Dobbie *et al.*, 2011). Patterned illumination in an excitation plane orthogonal to the observation axis has also recently been demonstrated to provide this increased resolution, but with greatly improved speed, depth of penetration, and reduced phototoxicity (Gao *et al.*, 2012). Stimulated emission depletion (STED) microscopy similarly constrains excitation, but in this case in a point-scanning system: a 'donut' of light is used to deplete fluorescent molecules from their excited state around the periphery of the diffraction-limited excitation beam. This leads to the effective shrinking of the 'spot' of excited fluorescence from ~250 nm down to ~50 nm, and can now be achieved along the optical axis as well as laterally (Hell *et al.*, 2008). STED has been successfully applied to fluorescent protein samples in living cells, and has even allowed 3D imaging of structural dynamics in the endoplasmic reticulum that are ordinarily occluded by the diffraction limit (Hell *et al.*, 2008), as well as *in vivo* time-lapse imaging of dendritic spines in the living mouse brain (Berning *et al.*, 2012).

The second broad method involves imaging of individual fluorescent molecules; although the light emitted from a single protein produces a diffraction-limited spot, the predictable profile of this point spread function permits the localization of the molecule to be determined at a far higher precision – typically on the order of ~20 nm for the number of photons emitted by a fluorescent protein (Hell, 2008). Armed with this information, the precise position and dynamics of individual GFP-conjugated molecules can be calculated, allowing the molecule to be tracked (Figure 6), and parameters such as diffusion coefficients or membrane binding times to be calculated (Mashanov *et al.*, 2004). Of course, the trick with experiments such as this is to ensure that isolated single molecules can be observed (since two or more fluorescent molecules separated by less than the diffraction limit will appear as a single spot), requiring careful control of expression levels. However, the use of PA-FPs and PC-FPs allows limited activation of a sub-pool of fluorescent proteins, requiring far less stringent control of the expression level (Manley *et al.*, 2008). As an added bonus, once the first cohort of activated molecules has been bleached or has left the imaged field, further cohorts can be activated iteratively, greatly increasing the density of data that can be generated from a single cell. This makes it possible to produce a 'road map' of the mobility of thousands of individual molecules at the cell surface (Manley *et al.*, 2008).

Another offshoot of this capacity to localize isolated single molecules with high precision from a larger pool of inactive PC-FPs or PA-FPs is that, by repeating this process many thousands of times, a very high-density map of the protein distribution emerges, which effectively constitutes a super-resolution image (Figure 7). In a fixed specimen, or a live specimen where the structure of interest will not move substantially over the imaging period, this forms the basis of photo-activation assisted localization microscopy, or PALM (Betzig *et al.*, 2006). It should be noted that through a variety of technical modifications the same principle can be applied to nongenetically encoded fluorescent probes, with a variety of different monikers such as stochastic optical reconstruction microscopy (STORM) (Manley *et al.*, 2011). Although this is a relatively slow mode of imaging compared to STED or SSIM techniques, PALM and its brethren allow the probing of cellular architecture with levels of resolution only previously achievable with the electron microscope (Betzig *et al.*, 2006).

Technical Considerations for Live Imaging

So far, we have explored some of the many different ways in which genetically encoded probes can be used to observe and measure the intricate inner workings of the cell. Now we will discuss some of the technical challenges that must be overcome in order to use these tools effectively. Consider the requirements for a successful experiment on single cells expressing a fluorescent protein-conjugated probe: to begin, the genetically encoded probe must be introduced and expressed by the cells. Next, we need to observe the cells on the instrument that will record the data – almost always a microscope for the purposes of this discussion. This brings us to several requirements for collecting high quality data; firstly, we need

Figure 6 Single-particle tracking with fluorescent proteins. Here, a HEK-293 cell is viewed in the plane attached to the coverslip (TIRF microscopy) whilst expressing a plasma membrane-bound lipid binding protein tagged with the photo-convertible fluorescent protein mEos2. Before conversion, mEos2 exhibits green fluorescence, but after low intensity illumination with violet light, a subset of individual molecules shift to orange/red emission, as shown in the larger image. The inset shows time lapse imaging (at approximately 50 ms intervals) of a single molecule moving on the surface of the cell membrane. This particle's position was calculated and tracked to produce the trajectory shown at top right, and used to calculate the mean square displacement over time. The dashed line on this plot shows the average mean square displacement over time for many thousands of such tracks from this cell, corresponding to a lateral diffusion coefficient of $0.3 \mu\text{m}^2 \text{s}^{-1}$. Scale bar = $5 \mu\text{m}$.

to be able to detect the signal with sufficient separation from the background noise to produce a clear image and/or accurate measurement. Secondly, this signal must be detected with sufficient temporal and spatial resolution to cover the cellular structure or process under investigation. Finally, fluorescence and cell health must be preserved for the entire duration of the experiment. Unfortunately, many of these requirements make contrary demands on the instrument, and the optimum compromise has to be found. We will briefly describe some of the major considerations in the following section.

With modern molecular biology, stable or transient introduction of new or modified genetic material into most cell types and organisms is possible, and often trivial. A detailed analysis of the state of the art of these methods is beyond the scope of this article, but we will briefly touch on one vital and sometimes overlooked consideration: the control of expression level. At first glance, it may seem that maximal expression of any given probe is desirable to generate the strongest signal. However, over-expression can have its own problems. For example, an over-expressed probe for a small molecule may introduce buffering effects, and an over-expressed protein conjugated to a fluorescent protein may saturate its endogenous binding partners and occlude its normal cellular distribution. Construction of fusion proteins can also be problematic: fusion of a fluorescent tag at the N- or C-terminus of a protein may occlude signal sequences or cause steric hindrance of other interactions necessary for proper targeting. Many of these pitfalls can also block essential cellular activities and eventually lead to toxicity. When designing experiments with genetically encoded fluorescent probes, it is therefore vital to design appropriate control experiments to ensure both that the probe itself is not perturbing the cell, and

that expression levels are not so high as to cause artifacts. That being said, a study of almost 900 human proteins showed that over 80% localize appropriately when over-expressed as GFP fusion proteins (Stadler *et al.*, 2013). Whereas both N- and C-terminal tags should be tested, Stadler *et al.* (2013) did report that C-terminal tags were less likely to cause protein mislocalization compared to the endogenous population.

The next consideration is to select the appropriate instrument for the experiment. Measurements of whole cell intensity or population responses measured with a biosensor may well be achieved with fluorescence-activated cell sorting or spectrometers, respectively. However, if subcellular detail or single cell responses are required, the light microscope is the tool of choice. Modern high-resolution fluorescence microscope systems are extremely costly items, usually in the realms of ~US\$100 000 to US\$1 million. Therefore, the choice of instrument is often dominated by availability. Nonetheless, a good understanding of the relative strengths of different systems is useful. But before we can choose the best microscope for the job, we need to consider the requirements of our experiment.

Having optimized expression of the probe, we need to ensure that we can record a sufficiently clear signal to generate a useful image or measurement. The technical boundaries of this consideration are constantly being pushed back, both in terms of the sensitivity of microscope cameras and photomultipliers, and the development of ever-brighter fluorescent protein derivatives and more sensitive biosensors. Therefore, it may well be possible to improve an experiment with newer reagents or equipment. Once a system has been chosen and optimized, we next need to consider the appropriate imaging parameters: essentially, the aim is to maximize the collected signal, and obtain the optimal spatial and temporal

Figure 7 Super-resolution imaging via photo-activation localization microscopy (PALM)/stochastic optical reconstruction microscopy (STORM). Here, a HEK-293 cell has fluorescent labeling of its microtubule cytoskeleton. Individual molecules are induced to fluoresce, and their positions are calculated and mapped. The process is repeated $\sim 10^4$ times, and the result of these 10^5 – 10^6 mapped molecular positions is a super-resolution image. The increased resolution is illustrated in the insets, in which individual microtubules are resolved in the PALM/STORM images. Scale bar = 5 μm .

resolution. Unfortunately, these three parameters offset one another (**Figure 8**); for example, obtaining the maximum signal-to-noise ratio requires either a longer exposure time (reduced temporal resolution) or collection of signal from a greater focal volume (reduced spatial resolution). In practice, we have to empirically determine the best compromise between these three parameters for each experiment. This is also where the choice of microscope system (if available) becomes important.

Most academic research environments have access to a confocal laser-scanning microscope, which is the most widely used microscope for imaging single cells. The term ‘confocal’ refers to the use of a pinhole, which effectively rejects out of focus light and is able to achieve spatial resolution

Figure 8 The competing parameters for optimal imaging. Increasing signal (more light collection) has to be balanced against temporal resolution (faster acquisition) and spatial resolution.

approaching Abbe’s limit. Modern systems are equipped with sensitive photomultiplier detectors and can easily achieve the maximum possible resolution with fluorescent protein probes at sufficient expression levels. However, if we refer back to **Figure 8** we can see that by rejecting out of focus light (improved spatial resolution), we must either sacrifice signal or else spend more time collecting light, reducing temporal resolution. Signal-to-noise or speed can be improved by opening the pinhole, which will lead to the collection of more light, with the offset that some axial resolution will be lost. Practically though, even with the brightest sample the physical speed with which the laser can be scanned across the specimen limits temporal resolution on these systems. Recently, resonant scanners have been incorporated into laser-scanning confocal microscopes, which greatly reduce scan-speed as a limit for imaging. Alternatively, spinning disk confocal microscopes sweep the entire field through an array of confocal pinholes mounted on the eponymous disk, sacrificing some axial resolution but with greatly enhanced sensitivity and speed of acquisition. A similar effect is achieved by sweeping a linear array of pinholes or a light sheet across the sample in swept field confocal microscopes. A special form of ‘confocal’ imaging can be performed by total internal reflection fluorescence (TIRF) microscopy ([Mattheyses et al., 2010](#)). In this case the illuminating laser light is directed to the specimen at an angle that yields an excitation only in a very thin layer (~ 100 nm) above the cover glass, resulting in fluorescence of the molecules that are in the plane of the cell attached to the cover slip. The advantage of this technique is its high signal to noise ratio to monitor processes at the ventral plasma membrane.

It should be noted that the popular and versatile laser-scanning confocal microscopes have the capacity to direct the diffraction-limited laser beam to anywhere in the sample. This makes FRAP and photoactivation-based experiments easy to perform on these systems. Furthermore, modern systems have such sensitive high-speed detectors that they are often capable of more advanced spectroscopic tasks, such as FCS/FCCS and FLIM.

An often cheaper but extremely sensitive option is to use a wide-field fluorescence microscope, where excitation light is focused onto the whole field of view, with no rejection of out-of-focus light. Despite the much poorer axial and lateral resolution compared to confocal microscopy, wide-field

has greatly improved sensitivity and temporal resolution (modern electron-multiplied charge-coupled device and scientific grade complimentary-metal-oxide-semiconductor cameras can achieve speeds exceeding 50 frames per second). This can make wide-field the choice for exceptionally dim and poorly expressing samples, or for many biosensors where sensitivity is the crucial parameter. Many FRET-based probes can exhibit fluorescence changes in the 5–10% range and the greatly increased sensitivity of wide-field systems produces much higher quality data.

Regardless of the microscope choice, the objective lens should be the best available. The higher the numerical aperture (NA), the more light will be collected, improving all three parameters listed in [Figure 8](#) – but with the caveat that the field of view and working distance will reduce as NA increases. The best NA objective available that can accommodate the sample should always be used!

Furthermore, the specimen must stay healthy, fluorescent and in focus for the duration of the experiment. High intensity light, especially laser light, can induce phototoxicity in cells. This becomes more severe the more blue-shifted (and hence, higher energy) the excitation light. Furthermore, repeated and/or high intensity illumination will cause fluorescent proteins to photobleach. Therefore, a balance has to be struck between maintaining the sample, and illuminating the sample enough to excite sufficient fluorescence. Again, compromise is necessary but as a rule, the minimum excitation intensity that produces satisfactory results should be used. Keeping cells healthy on the microscope stage involves maintaining them in a vessel bathed with appropriate medium. For experiments lasting a few minutes, balanced salt solutions are sufficient. For longer time periods, nutrient medium lacking phenol red (which is fluorescent and will occlude signal from the probe) can be used. The longer the incubation, the greater the care required with growth factors and serum, temperature and atmospheric conditions, and minimizing phototoxicity ([Coutu and Schroeder, 2013](#)). Maintaining focus can also be problematic with longer-term time-lapse imaging. Ensuring that the temperature of the microscope is equilibrated and the room is not subject to disruptive airflow from air conditioners or thoroughfare can help here. Conveniently, many modern microscopes are equipped with focal-feedback devices, which constantly measure the lens-specimen distance and automatically provide compensating adjustments.

When imaging in whole organisms, the above considerations are just as relevant; however, a whole host of additional technical issues must be taken into account. First, achieving optical access to the cells or structures of interest is often far from trivial. Precisely how this is best achieved depends on both the organism and cell type of interest. As mentioned above, LSM enables imaging of relatively transparent organisms without further intervention. In postnatal mammals, however, careful surgical exposure of the area to be imaged is typically required. For example, optical access to the rodent brain can be achieved either by thinning a small area of the skull to render it sufficiently transparent to image through ([Grutzendler et al., 2002](#)), or by replacing a small piece of the skull with a glass coverslip ([Trachtenberg et al., 2002](#)). Both procedures require extreme care and considerable technical expertise to avoid causing damage or inflammation, which could confound

experimental results. Similarly, dorsal skin-fold chambers provide optical access to implanted tumors ([Brown et al., 2001](#)). Where chronic imaging is to be performed over multiple days or weeks, animals must be carefully monitored for signs of infection and/or mechanical damage to any implanted imaging chamber. Furthermore, care must be taken to identify anatomical landmarks, such as surface blood vessel patterns, to enable the same cells to be relocated during subsequent imaging sessions. Where imaging in the live organism is not necessary, optical clearing techniques can provide an alternative approach. These chemical treatments reduce light scattering, usually by altering the refractive index of the specimen. Traditionally, clearing techniques have suffered from fluorescence quenching of fluorescent proteins and/or sample shrinkage or expansion, but newly developed methods are now circumventing these problems ([Chung et al., 2013](#); [Ke et al., 2013](#)).

Second, as mentioned above, mechanical stability is an absolute requirement for acquisition of high resolution and/or time-lapse images. In the living organism, motion artifacts from heartbeat, breathing and even pulsation of individual blood vessels can be problematic. In some cases these issues can be circumvented by mechanical stabilization, such as by head-fixation of rodents. In others, such as for soft tissue imaging, as is often the case in immunology or cancer biology studies, or where the experimental design necessitates the animal to move or perform behavioral tasks, it may be necessary to synchronize image acquisition to the heartbeat or respiration, and/or perform subsequent offline image correction. Covering or embedding the tissue of interest with agar can also help here; indeed, entire embryos are agar-embedded for long-term LSM.

Finally, great care must be taken to maintain the experimental subject in an optimal state, for both ethical and experimental reasons. Anesthetic agents must be carefully selected on the basis of their administration route, mode, and duration of action, and recoverability. Furthermore, a stable level of anesthesia must be maintained throughout the imaging session, and analgesics should be administered as required. Maintenance of body temperature and hydration are other key factors, especially for long-duration or repeated imaging sessions, and careful monitoring of physiological parameters may be necessary to produce optimal *in vivo* images.

Looking Forward

The use of genetically encoded fluorescent probes has come a very long way from the initial description of GFP in the 1970s. Even brighter fluorescent proteins are being developed with emission characteristics spanning the entire visible spectrum and beyond. These are being combined with ever more ingenious means of building them into biosensors for real-time, high-resolution reporting of molecular interactions and cellular activity. Combined with advances in the fields of molecular biology and optical physics, our capacity to image the molecular details of life inside cells is constantly improving. For an increasing number of problems in cell biology, the approach of simply watching how a process is driven by its protein components is now tenable. Whilst we anticipate that continued improvement along the lines discussed in this article will doubtless continue, we urge the reader to bear in

mind the relative obscurity of the crystal jelly that ultimately led to this explosion of progress in cell biology; in light of this, it would seem unwise to predict from where the next serendipitous technical revolution will emerge!

Total Internal Reflection Fluorescence Microscopy

D Axelrod, University of Michigan, Ann Arbor, MI, USA

© 2016 Elsevier Inc. All rights reserved.

Introduction

Total internal reflection fluorescence (TIRF) provides a means to selectively excite fluorophores in an aqueous environment very near a solid surface (within ≤ 100 nm). When adapted to microscopy, TIRF produces wide-field images with very low background fluorescence from out-of-focus planes. The surface-selective illumination and the unique polarization features of TIRF, often in simultaneous combination with other fluorescence techniques, have enabled numerous applications in cell biology. This article discusses the principles of TIRF microscopy and various methods (both commercial and homemade) to implement it. The applications discussed here are to biological cells, not to artificial membranes or to single molecules, about which there is also an extensive literature.

For a brief history of the technique and a literature review, see Axelrod (2008).

Theoretical Basis

When a light beam (see Figure 1(a)) propagating through a transparent medium 3 of high index of refraction (e.g., glass) encounters a planar interface with medium 1 of lower index of refraction (e.g., water), it undergoes total internal reflection for incidence angles θ (measured from the normal to the interface) greater than the 'critical angle' θ_c given by:

$$\theta_c = \sin^{-1}(n_1/n_3) \quad [1]$$

Figure 1 A TIR illumination. Refractive index n_3 must be greater than n_1 . The intermediate layer (consisting of metal or a dielectric material of refractive index n_2) is not necessary for TIR to occur, but can introduce some useful optical properties as explained in Axelrod (2013). Most applications of TIRF do not use an intermediate layer. The incidence angle θ must be larger than the critical angle θ_c for TIR to occur. The exponentially decaying evanescent field in the n_1 material is used to excite fluorophores in TIRF. The wavelength of the incident and reflected beams in the n_3 medium is λ_o/n_3 .

where n_1 and n_3 are the refractive indices of the liquid and the solid respectively (n_2 is reserved for intermediate layers, discussed in Axelrod, 2008). Ratio n_1/n_3 must be less than unity for TIR to occur. For 'subcritical' incidence angles $\theta < \theta_c$, most of the light propagates through the interface into the lower index material with a refraction angle (also measured from the normal) given by Snell's Law. (Some of the incident light also internally reflects back into the solid.) But for 'supercritical' incidence angles $\theta > \theta_c$, all of the light reflects back into the solid. Even in this case, some of the incident light energy penetrates through the interface and propagates parallel to the surface in the plane of incidence. The field in the liquid (sometimes called the 'evanescent wave') is capable of exciting fluorescent molecules that might be present near the surface.

The intensity I of the evanescent field at any position (measured as perpendicular distance z from the TIR interface) exponentially decays with z :

$$I(z) = I(0)e^{-z/d} \quad [2]$$

where,

$$\begin{aligned} d &= \frac{\lambda_o}{4\pi} (n_3^2 \sin^2 \theta - n_1^2)^{-1/2} \\ &= \frac{\lambda_o}{4\pi n_3} (\sin^2 \theta - \sin^2 \theta_c)^{-1/2} \end{aligned} \quad [3]$$

Parameter λ_o is the wavelength of the incident light in vacuum. Depth d is independent of the polarization of the incident light and decreases with increasing θ . Except for supercritical $\theta \rightarrow \theta_c$ (where $d \rightarrow \infty$), d is generally the order of λ_o or smaller.

Although the emission from a fluorophore excited by an evanescent field as viewed by a microscopic objective might be expected to follow an exponential decay with z according to eqn [2], this is not precisely true. Fluorescence emission near a dielectric interface (regardless of the means of excitation) is rather anisotropic and the degree of anisotropy is itself z -dependent (Hellen and Axelrod, 1987; Mertz, 2000; Axelrod, 2008, 2012). The fraction of the emission that can be captured by a fixed numerical aperture (NA) objective is therefore slightly z -dependent.

Applications and Combinations in Cell Biology

Cell/Substrate Contact Regions

TIRF can be used qualitatively to observe the position, extent, composition, and motion of contact regions even in samples in which fluorescence elsewhere would otherwise obscure the fluorescent pattern (Axelrod, 1981; Weis *et al.*, 1982; Joos *et al.*, 2006). The specific biochemistry of focal adhesions, using fluorescent proteins, has been studied with TIRF (Cohen *et al.*, 2006; Partridge and Marcantonio, 2006).

Figure 2 EPI vs. objective-based TIR fluorescence digital images, excited with an argon laser beam of wavelength 488 nm entering the side illumination port of an Olympus IX-70 microscope and viewed through an Olympus 1.45 NA 60X objective. This bovine chromaffin cells contains secretory granules marked with GFP-atrial natriuretic protein.

A variation of TIRF to identify cell–substrate contacts involves doping the solution surrounding the cells with a non-adsorbing and nonpermeable fluorescent volume marker; focal contacts then appear relatively dark (Gingell *et al.*, 1987; Todd *et al.*, 1988).

Secretory Granule Tracking and Exocytosis

Secretory granules often reside through the whole depth of a cell. When viewed with standard EPI-illumination, fluorescence-marked secretory granules are difficult to distinguish individually (Figure 2(a)). When viewed with TIRF, the granules closest to the membrane appear very distinctly (Figure 2(b)). The thin evanescent field allows small motions of individual fluorescence-marked secretory granules to manifest as small intensity changes arising from small motions in the direction normal to the substrate and plasma membrane (the ‘axial’ or ‘z-direction’). The precision of such axial tracking can be as small as 2 nm, much smaller than the light microscope resolution limit. Because of the high contrast and low background, the position of the centers of granules can be measured with an accuracy down to about 10 nm and motions much smaller than the granule diameter can be followed before and after exocytosis-inducing chemical stimulation (Allersma *et al.*, 2004, 2006). In some cases, dispersal of granule contents can be observed and interpreted as exocytosis and events immediately preceding and following exocytosis can be characterized (see Burchfield *et al.*, 2010 for a review; Weiss *et al.*, 2014a).

Most of the TIRF studies on the detailed mechanism of secretion have been on animal cells. However, the same techniques can be applied to plant cells, and in particular, have been applied to study secretion from pollen tubes (Wang *et al.*, 2006).

Cytoplasmic Filaments

Although TIRF cannot view deeply into thick cells, it can display with high contrast the fluorescence-marked sub-membrane filament structure at the substrate contact regions. Actin polymerization and its regulation, both *in vitro* and *in vivo*, have been studied by TIRF (see Manneville, 2006 for a review), as have microtubules (Shaw *et al.*, 2007) and microtubule-associated kinesin (Seitz and Surrey, 2006). The manner by which extracellular components such as fibronectin are organized through the membrane in concert with sub-membrane filaments can be investigated by TIRF (Yoneda *et al.*, 2007). In combination with very low levels of specific filament labeling, which produces fluorescent speckles, TIRF illumination can visualize filament subunit turnover (Adams *et al.*, 2004).

Calcium Channels and Transients

TIRF is completely compatible with standard EPI-fluorescence, bright field, dark field, or phase contrast illumination. These methods of illumination can be switched back and forth rapidly with TIRF by electro-optic devices to compare membrane-proximal ionic transients and deeper cytoplasmic transients (Omann and Axelrod, 1996). TIRF can be used to visualize single Ca^{2+} channels with good spatial and temporal resolution (Demuro and Parker, 2004).

TIR Combined with Polarization: Plasma Membrane Deformation

The polarization (i.e., the vector direction of the electric field) of the evanescent wave depends on the incident light polarization, which can be either ‘p-pol’ (polarized in the plane of incidence formed by the incident and reflected rays, denoted

Figure 3 Polarization of the evanescent field. (a) P-pol incident field, giving rise to a p-pol evanescent field, with phase lag δ_p and coordinate system convention indicated. The p-pol evanescent field is elliptically polarized in the x-z plane as shown (primarily polarized in the z-direction with a weaker x-component at a relative phase of $\pi/2$). (b) S-pol incident field, giving rise to s-pol evanescent field, with phase lag δ_s indicated. The phase lags $\delta_{p,s}$ are not equal to each other.

here as the x-z plane) or 's-pol' (polarized normal to the plane of incidence, here the y-direction). In both polarizations, the evanescent wavefronts travel parallel to the surface in the x-direction.

For p-pol incident light (see [Figure 3\(a\)](#)), the evanescent electric field vector direction remains in the plane of incidence,

Figure 4 Polarized excitation TIRF at a membrane deformation. This is a schematic view of the excitation probability of oriented carbocyanine fluorophores embedded in a membrane in a z-polarized evanescent field (the dominant direction of a p-pol evanescent field). The membrane is depicted in cross section with a curved region corresponding to an inward deformation. The direction of absorption dipole of the fluorophores is shown with bidirectional arrows. Higher excitation probability is depicted by lighter shades. The z-component of the electric field selectively excites the regions of oblique membrane orientation.

mainly in the z-direction but with a small component in the x-direction depending on the incidence angle. For s-pol incident light (see [Figure 3\(b\)](#)), the evanescent electric field vector direction remains purely normal to the plane of incidence (the y-direction).

In standard normally incident EPI illumination, the incident light has no z-component. This unique z-direction found in p-pol TIR can be used to view submicroscopic deformations in the plasma membrane of living cells. For example, a membrane label might be chosen because its excitation dipole is always parallel to the membrane surface ([Axelrod, 1979](#)). By using excitation light that is polarized in the z-direction, perpendicular to the surface, only those regions of the plasma membrane that are not parallel to the substrate will be excited ([Figure 4](#)). To normalize against spatial-intensity variations that arise from actual place-to-place fluorophore-concentration differences, an 's-pol' TIR beam is also used to acquire an alternate image of each scene. The ratio of images taken with sequential p- and s-pol excitation is then calculated; the 'p/s' result reports only orientational effects and not local concentration effects.

With polarized excitation TIRF, along with a second label to mark the location of secretory granules, dynamic changes in membrane deformation can be tracked during the course of a secretion event ([Anantharam et al., 2010, 2012](#)).

TIR Combined with Fluorescence Recovery after Photobleaching and Fluorescence Resonance Energy Transfer (FRET)

TIR combined with fluorescence recovery after photobleaching (FRAP) can examine the specific or nonspecific binding kinetics of proteins to cellular membranes ([Hellen and Axelrod,](#)

1991; Stout and Axelrod, 1994; Sund and Axelrod, 2000). The post-bleach recovery can be quantitatively observed at each camera pixel to obtain a spatially-resolved 'image' of kinetic rates (Axelrod and Omann, 2006). TIR-FRAP has also been used to determine the diffusion coefficient of proteins inside single secretory granule in primary chromaffin cells (Weiss *et al.* (2014b)).

Interactions among channel or receptor proteins at surfaces can be studied by TIR/FRET (Khakh *et al.*, 2005).

TIR Combined with Interference Reflection Contrast

Interference reflection microscopy is a nonfluorescence method of visualizing the closeness of cell/substrate contact regions. By combining TIRF with interference reflection contrast (IRC), Ca^{2+} microdomains can be viewed simultaneously with exocytosis events in synapses (Beaumont *et al.*, 2005). Both TIR and IRC were used on the same sample to study the approach of neuronal growth cones to the substrate (Tatsumi *et al.*, 1999).

Optical Configurations and Setup

Many alternative optical arrangements for TIRF are available. Some configurations use a high NA ($\text{NA} > 1.4$) microscope objective for both TIR illumination and emission observation ('objective-based'), and others use a prism to direct the light toward the TIR interface with a separate objective for emission observation ('prism-based'). The evanescent illumination is not 'pure' with objective-based TIRF: a small fraction of the illumination of the sample results from excitation light scattered within the objective, and a small fraction of the observed fluorescence arises from luminescence of the objective's internal elements. Prism-based TIRF avoids these problems but geometrical constraints leave it most workable only for low- and medium-power objectives.

This section gives examples of these arrangements. We assume that the sample consists of fluorescence-labeled cells in culture adhered to a glass coverslip.

High Aperture Objective-Based TIR

By using an objective with a sufficiently high NA, supercritical angle incident light can be cast upon the sample by illumination through the objective (Stout and Axelrod, 1989; Axelrod, 2001). Although an arc lamp can be used as the light source, the general features are best explained with reference to a laser source.

The laser beam used for excitation is focused (by an external focusing lens) to a point at the back focal plane of the objective so that the light emerges from the objective in a collimated form (i.e., the 'rays' are parallel to each other). This insures that all the rays are incident upon the sample at the same angle θ with respect to the optical axis.

The point of focus in the back focal plane is adjusted to be off-axis. There is a one-to-one correspondence between the off-axis radial distance ρ and the angle θ . At a sufficiently high ρ , the critical angle for TIR can be exceeded. Further increases in ρ

serve to reduce the characteristic evanescent field depth d in a smooth and reproducible manner.

The NA of the objective must be greater than the refractive index of the sample to reach the critical angle and beyond. The 1.49NA objectives are probably the method of choice for TIR except for cells which have particularly dense organelles. Dense organelles tend to scatter the evanescent field, and this effect is less prominent with the higher angles of incidence accessible through higher aperture objectives.

The angle of convergence/divergence of the laser beam cone at the back focal plane is proportional to the diameter of the illuminated region subsequently created at the sample plane. Large angles (and consequent large illumination regions) can be produced by use of a beam expander placed just upstream from the focusing lens.

Custom-built TIRF systems generally use a free laser beam rather than fiber optics because this allows more accessible control of polarization and more rapid control of incidence direction with electrooptical devices. Figure 5 shows an example of such a system, suitable for both two-color TIRF and polarized excitation TIRF. Positioning of the laser beam focus at the desired off-axis location at the back focal plane is greatly facilitated by some fast electro-optical beam deflector system. For example, a pair of computer-controlled acousto-optical modulators or small galvanometer mirrors can adjust the focal point to any position in the two-dimensional back focal plane. Since altering the focus position at the back focal plane (to alter the incidence angle at the sample) should preferably leave the illumination region on the sample plane unmoved, it is desirable to place the deflector system at a plane in the optical system equivalent to the sample plane.

Commercial TIRF laser systems generally use enclosed fiber optics, need less expertise for setting up and maintaining alignment, and contain shut-off interlocks for laser safety. The tip of the optical fiber acts like a point source placed at an equivalent back focal plane (EBFP). The optical fiber tip itself is mounted on a micrometer translator to move from positions corresponding to subcritical incidence angles (EPI) to supercritical incidence angles (TIR). Figure 6 shows an example.

Commercial arc-lamp TIRF systems use an off-axis curved slit cutout at an EBFP. The slit is positioned off-axis to transmit only a thin-curved band of light at a radius that will produce supercritical angles. To optimize the throughput, the brightest part of the Hg arc is focused off-axis right upon the curved slit cutout, with a focusing aberration that curves the arc image to match well with the curved slit.

Prism-Based TIRF

Although a prism may restrict sample accessibility or choice of objectives in some cases, prism-based TIR is very inexpensive to set up and produces a 'cleaner' evanescent-excited fluorescence (i.e., less excitation light scattering in the optics) than objective-based TIR. Figure 7 shows several schematic drawings for setting up laser/prism-based TIR in an inverted or upright microscope.

A commercially available variation of prism-based TIR uses a high-aperture condenser fed with laser light from an optical fiber tip instead of a custom-installed prism fed by a free laser

Figure 5 Optical ray diagram for custom-built TIRF with a free laser beam. This shows the basic setup and also optional add-ons for polarized excitation TIRF and for two excitation color TIRF. For the basic setup, the laser beam enters the microscope (lower right) through the rear hole in the microscope tower (dark gray) that was designed for arc illumination. For pictorial clarity, a collimated beam is shown here emerging from the sample plane at an oblique (but sub-TIR) angle, after having focused off axis at the objective (OBJ) BFP. Lens L3, placed in the small open space between the tower and the dichroic mirror (DM2) holder, ensures that the incoming beam focuses at the BFP with as large an angle of convergence as possible. (Large angles create a large illuminated region on the sample.) The off-axis focus position on the BFP (and the corresponding super- or subcritical incidence angle at the SP) is controlled by the angle of an electronically driven dual galvanometer mirror set (GM) positioned at an equivalent sample plane immediately behind the tower. Upbeam from the GM, the beam is focused by lens L2 to a point on an EBF that was formed there by the placement of lens L3. As usual for fluorescence microscopy, the sample plane is reimaged (see dashed red line) at the camera CCD array by lens L4 in the microscope/camera coupler. For the two-excitation color add-on, the second color is added via a DM1 and shuttered by SH3. The complication is that simple lenses L2 and L3 will have a chromatic aberration (shorter focal lengths) for blue vs green light. The appropriate EBF cast by lens L3 will thereby have slightly different positions for the two colors. Lens L1 placed upbeam in the blue beam is selected and positioned to ensure that both the colors are focused by L3 at the actual BFP. For the polarization control add-on option in the green beam, a quarter-wave plate converts the (presumably) vertical polarization emerging from the laser into circular polarization (CIRC). The first polarizing cube (PC1) divides the beam into its two polarization components, horizontal (H, straight ahead) and vertical (V, reflected 90°). Each is permitted to pass or be blocked by its own shutter (SH1 and SH2). The polarization paths are combined in a second polarizing cube (PC2).

Figure 6 Laser illumination introduced by an optical fiber through the rear port normally used by the arc lamp. This scheme is employed by commercial TIRF systems.

beam. This system has the advantage of ready-made convenience and easy variation of both polar and azimuthal incidence angle adjustment, but is limited in maximum incidence angle.

In all the prism-based methods, the TIRF spot should be focused to a width no larger than the field of view. The larger the spot, the more the spurious scattering and out-of-focus fluorescence from the immersion oil layer between the prism and coverslip will increase the generally very low fluorescence background attainable by TIRF. Also, the incidence angle should exceed the critical angle by at least a couple of degrees. At incidence angles very near the critical angle, the cells cast a noticeable 'shadow' along the surface.

Additional Features

Suppression of Laser Interference Fringes

Laser illumination (whether TIRF or EPI) can produce annoying interference fringes because optical imperfections in the beam path can shift the local phase of coherent light. For critical applications, several approaches can alleviate the problem. One approach employs an optical fiber bundle in

Figure 7 Schematic drawings for prism-based TIR, all using a laser as a light source. The vertical distances are exaggerated for clarity. The first four configurations (a)–(d) use a TIR prism above the sample. Configuration (e) places a small triangular prism below the sample off to the side and depends on multiple internal reflections in the substrate to bring the illumination into the field of view. Configurations (f) and (g) are for an upright microscope. In (f), a high-aperture condenser plays the role of an external prism. Configuration (g) utilizes the integral optics in the microscope base and a trapezoidal prism on the vertically movable condenser mount.

which individual fiber-to-fiber length differences exceed the laser light's coherence length. This produces an extended source at the output tip with point-to-point relative phases that are temporally randomized and defocused on the sample (Inoue *et al.*, 2001). This elegant system, with no moving parts, produces a speckle pattern that changes so rapidly that it appears uniform down to the nanosecond timescale. Commercially available mode scramblers and rapid flexing of optical fibers may also reduce some fringing.

Another set of methods is appropriate for a free laser beam rather than optical fiber system. For example, a finely frosted glass surface or a plastic plate (such as tissue culture dish bottom), spinning normally to the laser beam, temporally

randomizes the phase and produces a fringe pattern that fluctuates and can be averaged over the duration of a camera exposure (Kuhn and Pollard, 2005).

Interference fringes can be effectively suppressed by spinning the azimuthal angle of TIR incidence with electro-optical or mechano-optical devices such that the incident beam traces a circle where it focuses at the objective's back focal plane (BFP). Only one azimuthal direction illuminates the sample at any instant. However, the spinning period is much shorter than the camera's exposure time or retinal image retention time. Therefore, the interference fringes appear superimposed in their intensities, giving the illusion of a much more uniform illumination field (Mattheyses *et al.*, 2006).

Actual Evanescent Field Depth and Profile

The evanescent field characteristic depth in an actual sample may deviate from that predicted by eqn [3] for several reasons even if the incidence angle θ is well measured. Depth d depends on the refractive index of the liquid sample above the TIR surface, and this is not well known for samples such as local regions of cell cytoplasm. So far, no good way of accurately measuring the local evanescent field depth and profile in an actual cell has been implemented.

Measurements of evanescent depth in a homogeneous artificial sample with a refractive index that approximated the average in a heterogeneous sample can be done. In such a sample, the characteristic time for diffusion of fluorescent beads through the evanescent field (possibly by TIR/FRAP) can be measured and (given a known diffusion coefficient) converted to a corresponding characteristic distance. However, this method gives only a single number for effective depth but does not provide unambiguous information about the possibly non-exponential intensity profile as a function of z .

In samples with heterogeneous refractive index, regions with higher index may not support TIR, whereas lower index regions do. Clearly, it is best to illuminate with as high an incidence angle as possible to be sure that all regions support TIR. Even if the incidence angle is sufficiently high to support TIR everywhere, irregularities and heterogeneities in the sample give rise to scattering of the evanescent field. This scattered light can excite fluorescence as it penetrates much more deeply into the liquid than does the evanescent light. The effect is much less pronounced for higher TIR incidence angles.

The TIR optics itself, particularly the high aperture objectives used in objective-based illumination, can produce scattered light. Actual intensity profiles arising from objective-based TIR can be obtained by observing a large ($\sim 8\ \mu\text{m}$ diameter) spherical bead with a refractive index matched to the surrounding liquid to avoid disruption and scattering. The bead can be fluorescence-labeled on its surface. At the image of the point of contact between the bead and the TIR substrate, the fluorescence is the brightest. It becomes dimmer with increasing distance in the TIR plane from the contact point. Simple geometry then allows calculation of the fluorescence versus z . In an actual test of this method in 1.45NA and 1.65NA objective-based TIRF (Mattheyses and Axelrod, 2005), the evanescent field was found to account for about 90% of the intensity at $z=0$, and the exponential decay depth agreed well with expectations based on angle and refractive indices. However, a much slower decaying component, presumably from scattering within the objective, was also evident, and this component became dominant in the distant $z > 2d$ zone.

Apart from this dim scattering component, bright collimated shafts of scattered light, emanating from the edge of the top lens of the objective, can be seen in objective-based TIR. Fortunately, however, these shafts do not cross the field of view so they do not excite spurious fluorescence in the image.

Variable Incidence Angle TIR: Concentration Profiles

By decreasing the supercritical incidence angle back toward the critical angle, the depth of the evanescent field increases,

reaching out to more distal fluorophores. By measuring the fluorescence observed as a function of supercritical incidence angle, it is thereby possible to deduce what is the concentration profile $C(z)$ of fluorophores within the evanescent field, to a resolution much shorter than the evanescent field depth. This approach has been employed in practice to measure cell surface-to-substrate separation distances (Loerke *et al.*, 2000; Stock *et al.*, 2003) and the z -position of subcellular organelles (Loerke *et al.*, 2002).

Long-Term Fluorescence Movies of Cultured Cells

Since the cells are exposed to TIR excitation light only at their cell/substrate contact regions but not through their bulk, they tend to survive longer under observation, thereby enabling time-lapse recording of a week in duration. During this time, newly appearing cell surface receptors can be immediately marked by fluorescent ligand that is continually present in the full cell culture medium. Because TIRF is utilized, background fluorescence from this bath of unbound fluorophore is minimized (Wang and Axelrod, 1994).

TIRF versus Other Optical Sectioning Microscopies

TIRF is only one of several optical sectioning techniques enjoying wide use in microscopy, including confocal and multiphoton microscopies. Each has particular distinct advantages and drawbacks.

Confocal microscopy achieves axial selectivity by exclusion of out-of-focus emitted light with an image plane pinhole. Confocal microscopy has the clear advantage in versatility; its method of optical sectioning works at any plane of the sample, not just at an interface between dissimilar refractive indices. However, other differences exist which, in some special applications, can favor the use of TIRF.

- The depth of the optical section in TIRF is typically $\leq 0.1\ \mu\text{m}$, whereas in confocal microscopy it is relatively thick ($\sim 0.6\ \mu\text{m}$).
- In some applications (e.g., FRAP, fluorescence correlation spectroscopy, or on cells whose viability is damaged by light), illumination and not just detected emission is best restricted to a thin section; this is not possible with standard confocal.
- TIRF can be adapted to and made interchangeable with existing standard microscope optics, even with 'homemade' components. It is much less expensive than confocal microscopy, even for the commercial systems

Two-photon (or more generally, multiphoton) microscopy has many desirable features, including true optical sectioning, whereby the plane of interest is the only one that is actually excited, as in TIRF. Multiphoton microscopy is not restricted to the proximity of an interface, but its optical section depth is still several times thicker than that of TIRF. The setup expense of multiphoton microscopy for an infrared laser with sufficient pulse peak intensity can also be a consideration. Both multiphoton and confocal microscopy are necessarily scanning techniques; TIRF microscopy is a 'wide field' technique and is

thereby not limited in speed by the scanning system hardware or image reconstruction software.

Glossary

Localization The two- or three-dimensional positional determination of a point source.

PSF The detection system's characteristic diffraction-limited image of a point source.

Resolution The smallest distinguishable distance between two point sources.

Introduction

Fluorescence microscopy is a popular imaging technique both for its relatively noninvasive properties and its ability to simultaneously image multiple species in living cellular specimens. Images are formed by the simultaneous observation of many fluorescing molecules to visualize cellular structures and processes. In conventional far-field fluorescence microscopy, the spatial resolution is diffraction-limited. Thus, the smallest resolvable details are given by the Rayleigh criterion, namely

$$r_0 \geq \frac{0.61\lambda}{NA}$$

where r_0 is the distance between point sources, λ is the wavelength of the photons detected and NA is the numerical aperture of the lens system (Born and Wolf, 1997). In fluorescence light microscopy, typical lateral and axial resolutions are ~ 200 nm and ~ 600 nm, respectively. Thus, in diffraction-limited microscopy, the size and spatial organization of cellular structures on length scales smaller than the diffraction limit remain unresolved.

Many important biological processes occur on length scales shorter than the diffraction limit, and the motivation to improve optical resolution in fluorescence microscopy has been strong. Fortunately, one can observe these phenomena through the use of localization-based super resolution techniques: stochastic optical reconstruction microscopy (STORM) (Rust *et al.*, 2006), photoactivatable localization microscopy (PALM) (Betzig *et al.*, 2006), and fluorescence photoactivation localization microscopy (FPALM) (Hess *et al.*, 2006). These and related techniques have recently become quite popular. Eric Betzig, inventor of PALM, Stefan W. Hell, and William E. Moerner, received the 2014 Nobel Prize in chemistry for their contributions to super resolution microscopy in biological imaging (Nobel Media AB, 2014).

Concept

Localization microscopy is made possible by labeling samples with specific fluorescent molecules that can be converted from a dark to bright state and eventually to another dark (bleached) state (Figure 1). Within the sample, an activation laser is used to potentiate the fluorescence of small subsets of single molecules. A second, readout laser excites the

fluorescence of those molecules so that they are imaged as diffraction-limited point-spread functions (PSFs) (Figures 1(a)–1(c)). During imaging, or, more typically after imaging, the molecular images are mathematically analyzed to determine the two- or three-dimensional coordinates of each identified molecule, which is called localization (Figures 1(e)–1(g)). One controls the molecular activation and bleaching rates to allow only a small number of molecules to be visible at once, and to cause those molecules to be separated by a distance greater than r_0 . Two-dimensional plots of this information constitute the image (Figure 1). Localization microscopy can improve the diffraction-limited resolution by about a factor of 10 or more (Figures 1(d) and 1(k)). This enables the elucidation of biological structures on sub-diffraction length scales.

Localization microscopy can image individual fluorophores as well as multiple fluorophores simultaneously (Bossi *et al.*, 2008; Testa *et al.*, 2010; Gunewardene *et al.*, 2011). Molecular orientations (Gould *et al.*, 2008), and localizations in two or three dimensions (Juette *et al.*, 2008; Huang *et al.*, 2008), can also be determined. Multicolor, molecular orientation and three-dimensional imaging require specific modifications to the detection path, involving the use of specialized optics (Figure 2) and methods (see Experimental Methods).

Super resolution imaging can be performed in live cells (Hess *et al.*, 2007) and fixed samples. Fixed cell imaging reveals static information about the size and spatial organization of the labeled structures at one instant in time. Live cell imaging reveals dynamics of cellular structures and enables the measurement of single molecule trajectories on millisecond timescales (Gudheti *et al.*, 2013; Manley *et al.*, 2008).

Experimental Methods

For particular functionalities, the microscope can be aligned to match one of the possible layouts in Figure 2. The activation laser, which frequently has a 405 nm wavelength, should be adjusted to spatially overlap with the readout laser. The readout wavelength can be one or several different wavelengths, chosen to best excite the fluorescent molecules in the sample. For example, the photoactivatable fluorescent protein Dendra2 is excited well by a 556 nm or 561 nm laser, whereas Alexa647 is optimally excited at 647 nm. Both lasers are

Figure 1 The concept of FPALM is shown using simulated single molecules. Diffraction-limited single molecules are sparsely activated, excited, and imaged before they photobleach (a). Photobleached molecules are replaced in each frame by newly activated single molecules (b,c). Together, all of the single molecules form a diffraction-limited image (d). The recorded single molecules in (a–c) are mathematically localized (e–g, enclosed in yellow circles). The cumulative sum of the localized molecules form super-resolved images (h–k). Sparse numbers of molecules (h,i) do not adequately define the structures as well as larger numbers of molecules (j,k). Scale bar in (d) is 1 μm and is the same for all images.

typically focused by a lens into the back aperture of the objective in order to achieve widefield illumination at the sample.

The lateral position of the laser as it enters the objective affects the excitation profile at the sample. In **Figure 2** panel I, the path of the laser lies directly on the optical axis, which results in excitation through the sample. By shifting the path of the laser laterally away from the optical axis, the laser beam becomes inclined in the sample, as seen in panel II. Further shifting of the laser from the optical axis puts the excitation into total internal reflection fluorescence (TIRF) mode, as seen in panel III. In TIRF, the evanescent electric field penetrates only a few hundred nanometers into the sample, enabling excitation of only molecules very close to the surface of the coverslip and greatly reducing out of focus background.

The objective collects a portion of the excited fluorescence, which then passes through the dichroic, and is then focused by the tube lens to form an image in an intermediate plane, where an aperture is placed to crop the area imaged. Two additional lenses form a telescope that magnifies and focuses the cropped image onto the camera. Modifications to the detection path increase the amount of information measured from the single molecules. In **Figure 2(a)**, the fluorescence signal is imaged directly onto the camera and provides two-dimensional spatial information.

Simultaneous multicolor imaging, i.e., the labeling of a sample with multiple spectrally distinct species of fluorescent molecules, can be done using the optical setup shown in **Figure 2(b)** (Bossi *et al.*, 2008; Testa *et al.*, 2010;

Figure 2 Basic layout of an FPALM setup and many modifications. The Readout and Activation laser on/off and powers are controlled by shutters, SH, and neutral density filters, ND, respectively. The lasers are combined at DM1 and reflected to the lens, L1, by mirrors M2 and M3. The lasers pass through a quarter wave plate, QWP, for conversion to circularly polarized light, then reflect off the filter cube dichroic, DM2, and focus at the back aperture of the objective, OBJ. The lateral position of the lasers at the back aperture of the objective controls the angle at which the lasers enter the sample: (I) centered for excitation perpendicular to the coverslip, (II) slightly offset for inclined beam in the sample, and (III) offset for TIRF. The lateral position of the laser is adjusted by shifting the translation stage, TS. Sample fluorescence is collected by the objective, passes through DM2, and is focused by the tube lens, TL. Outside the microscope, additional bandpass filters, F2, remove background. The aperture, AP, reduces the image region. The image is expanded by the telescope lenses, L2 and L3, before entering the detection box. Modifications to the detection path enable different modes of imaging. For single color imaging, fluorescence is measured directly by the camera (a). For simultaneous multicolor imaging, a dichroic, DM3, separates the fluorescence into two channels (b). Additional mirrors, M5 and M6, ensure the same focal plane is imaged. For three-dimensional imaging by the biplane method, the fluorescence is split by a 50:50 beam splitter, BS, with M8 redirecting reflected fluorescence to the camera (c). The different path lengths result in two different focal planes imaged at the camera. For three-dimensional images by astigmatism, a cylindrical lens is placed in the detection path (d). To measure anisotropy, a polarizing beam splitter, PBS, splits fluorescence depending on polarization, with M9 and M10 ensuring path-length equality (e). Light from the Mercury Lamp passes through a filter, F1, and expands with the telescope lenses L4 and L5. A flip mirror, FM, reflects the mercury lamp light into the microscope.

Gunewardene *et al.*, 2011). The dichroic splits the fluorescence into two color channels and the mirrors adjust the path lengths so that the same focal planes are imaged in side-by-side areas on the camera. The ratio of intensities between the two channels can be used to distinguish the different fluorescent species in the image.

Three-dimensional imaging requires a method to break the axial symmetry of the PSF. Breaking the symmetry can be done by a variety of methods (Juette *et al.*, 2008; Huang *et al.*, 2008; Pavani *et al.*, 2009; Shtengel *et al.*, 2009). Here, we show the two easiest methods to implement: Biplane (Juette *et al.*, 2008) in Figure 2(c) and astigmatism (Huang *et al.*, 2008) in Figure 2(d). The Biplane method splits the fluorescence

with a 50:50 beam splitter cube so that two different focal planes are imaged on the camera. This provides two separate measurements of the single molecule enabling axial localization. The fluorescence path lengths are different for each channel, resulting in two different focal planes being imaged on the camera. The differences in shape of the molecular images in the two channels enable the localization of the axial position of the molecule. The astigmatism method introduces a cylindrical lens into the detection path as seen in Figure 2(d). The cylindrical lens changes the focal length along only one of the lateral directions. The image of the single molecule will be stretched either horizontally or vertically depending on its axial position. This stretching is then

mathematically modeled to determine the molecular position in three dimensions.

The anisotropy, or dipole orientation, of the imaged single molecules can be measured using the setup in [Figure 2\(e\)](#) ([Gould *et al.*, 2008](#)). The fluorescence is split by a polarizing beam splitter cube and the mirrors adjust the path lengths so that the same focal planes are imaged on the camera. The ratio of intensities between the two channels enables determination of the azimuthal (in-plane) angle of the dipole of the single molecule.

Preparation of samples can follow standard protocols for fluorescence labeling, however, several crucial details need to be considered. Photoactivatable single molecules, by nature, are sensitive to light. Once labeled, samples should be shielded from stray light sources (room lights, incubator UV, etc) which may prematurely activate single molecules. Additionally, sample media and buffers often contain auto-fluorescent components which serve to increase background noise and worsen the localization precision. Sample media and buffers should be made such that auto-fluorescent components are removed or replaced with nonfluorescent alternatives.

For any multichannel or three-dimensional imaging modality, calibration data should be recorded. Multichannel calibration typically consists of bead images which can be used to create a mathematical transform to overlay the two channels. Three-dimensional calibration data requires precise positioning of beads in order to generate an axial calibration curve.

Data Analysis

Typical localization-based super resolution datasets consist of between a few hundred and several tens of thousands of image frames of single molecules. The crucial point of the technique is to measure spatially well-separated fluorescent single molecules in each frame, as seen in [Figures 1\(a\)–1\(c\)](#). As the single molecules photobleach and the pool of inactive molecules decreases, the activation intensity should be increased so that the density of active single molecules remains roughly constant during the imaging sequence.

Plots of localized single molecules are shown in [Figures 1\(e\)–1\(g\)](#). Localization algorithms read in raw data and output a list of localized particle positions. These involve background subtraction before each single molecule is identified and localized. The typical algorithm first involves a calculation of the effective pixel size by using a scale image to determine how many pixels fit in a known image area. Background noise is calculated by measuring the variation of detected fluorescence within a nearby region that does not contain any fluorescing molecules. Single molecules are then identified based on pixel intensity and mathematically localized either by using a least-squares fitting of a Gaussian, maximum-likelihood estimation of a theoretical PSF ([Mortensen *et al.*, 2010](#)) or fitting to the experimentally measured PSF ([Juetten *et al.*, 2008](#)). The identification and localization process repeats for all single molecules in the image. A first set of thresholds are applied to identify objects as bright as a single fluorophore. Objects that pass this first threshold are then localized. A second set of thresholds either discards, or sets aside for further analysis, the

PSFs that are substantially larger or smaller than the diffraction limit; or poorly localized based on goodness of fit and number of detected photons. A localization precision is then determined for each PSF to be analyzed, which depends on the number and emission wavelength of the number of photons detected from the fluorophore, the background noise per pixel and the effective pixel size.

For the detection setups in [Figures 2\(b\)–2\(e\)](#), the analysis algorithms must be modified to extract the appropriate and available information. For multichannel techniques ([Figures 2\(b\), 2\(c\), and 2\(e\)](#)), the two channels are overlaid using the calibration data. Single molecules are localized using the methods in the previous paragraph to determine the lateral localized positions. The ratio of intensities and/or the comparison of the shapes of the molecular images in the two channels reveals information such as the type, axial position, or dipole orientation of the single molecule. The images in [Figure 2\(d\)](#) form a single channel; the axial positions of the single molecules are extracted by measuring the horizontal and vertical widths of the PSF for each molecule within the image.

A final rendered image of all localized single molecules ([Figure 1\(k\)](#)) will have enhanced resolution in comparison to the diffraction-limited image ([Figure 1\(d\)](#)). Gaussian-based visualization was used to render the super resolution image in [Figure 1](#), but several other methods exist, such as scattergrams, quad-tree histograms, and Delaunay triangulation ([Baddeley *et al.*, 2010](#)).

For a more thorough discussion of the microscope setup, alignment, imaging, and analysis methods, see [Gould *et al.* \(2009\)](#), [Curthoys *et al.* \(2013\)](#).

Discussion

Localization microscopy can provide resolution at near molecular length scales, with time resolution of 0.1–0.03 s per rendered image ([Huang *et al.*, 2013](#); [Gunewardene *et al.*, 2011](#); [Shim *et al.*, 2012](#)). Because localization microscopy images single molecules, a number of different types of information can be obtained.

Live cell images can be obtained with frame rates of ~ 1 ms, allowing rendered images to be obtained within 0.1 s for fluorescent proteins (unpublished data) and 0.03 s for organic dyes ([Huang *et al.*, 2013](#)). Careful choice of excitation intensity can allow individual molecules to be imaged for multiple frames and thereby single molecule trajectories to be obtained ([Gudheti *et al.*, 2013](#); [Manley *et al.*, 2008](#)). From these trajectories, the diffusion or transport behavior of molecular species can be obtained for single species ([Hess *et al.*, 2007](#); [Manley *et al.*, 2008](#)), or combinations of species ([Gudheti *et al.*, 2013](#)). Multiple molecular species can be distinguished by splitting the detected fluorescence based on wavelength to form two or more simultaneous images, and using the ratio of intensities within those images to determine molecular type ([Bossi *et al.*, 2008](#); [Gunewardene *et al.*, 2011](#); [Testa *et al.*, 2010](#)). Alternatively, probes may also be distinguished based on activation or readout wavelength in addition to emission spectrum ([Bates *et al.*, 2007](#)). Finally, methods to quantify numbers of molecules or molecular

density are being developed (Manley *et al.*, 2008; Lee *et al.*, 2012; Wolter *et al.*, 2012; Avilov *et al.*, 2014).

Although a wide variety of information can be obtained from a biological sample, a number of parameters must be considered in order to optimize use of localization microscopy for such applications.

The molecular labeling density (Figures 1(h)–(k)) and localization have a profound effect on the ultimate quality (and resolution) of images obtained. The localization precision is strongly affected by number of detected photons per molecule, background noise per pixel, camera pixel size, and the width of the diffraction-limited PSF (Thompson *et al.*, 2002). Thus, minimization of fluorescence background and maximization of fluorescence detection efficiency are crucial. Minimization of other sources of image noise, such as pixel-to-pixel (spatial) (Pertsinidis *et al.*, 2010) and frame-to-frame (temporal) variation in camera sensitivity, are also important (Huang *et al.*, 2013). Based on the Nyquist sampling theorem, the density of labels should yield a nearest neighbor distance no larger than half the value of the desired resolution (Shroff *et al.*, 2007). More generally, the resolution can be defined in a number of ways (Betzig *et al.*, 2006; Hess *et al.*, 2006; Mukamel and Schnitzer, 2012; Nieuwenhuizen *et al.*, 2013). Recently, a resolution measure based on information content as a function of spatial frequency has led to a ‘Fourier ring correlation’ method, which quantifies the effects of localization precision and molecular density for a wide variety of conditions applicable to localization microscopy (Nieuwenhuizen *et al.*, 2013). Use of this method can be made through an ImageJ app.

To optimize image quality, molecular coordinates in localization microscopy datasets need to be corrected for axial and lateral sample drift, such as through the use of fiducials (Betzig *et al.*, 2006), cross-correlation of data subsets (obtained in fixed samples only) (Mlodzianoski *et al.*, 2011), or experimental modifications need to be made to prevent drift during acquisition, such as through autofocus and/or lateral stabilization of the microscope stage relative to the objective lens (Huang *et al.*, 2008).

For multicolor datasets, bleedthrough, defined as inadvertent identification of molecules of one species as another, can cause significant errors in interpretation of results (Kim *et al.*, 2013). Correction for misidentification rates of as little as a few percent is crucial if results are to be used for quantification of colocalization (Kim *et al.*, 2013).

In summary, localization microscopy is well-suited for imaging living and fixed cell specimens, and other biological samples, where fluorescent labels can be attached to the biomolecules of interest, where spatial resolution of tens of nanometers is desirable, and where a time resolution of 0.03 s or slower is sufficient. Molecular trajectories can also be obtained on millisecond timescales. Localization microscopy is to some extent limited by data analysis and the fluorescent labels used for imaging. Without considerable effort, immediate visualization is hindered by the data analysis required. Further development of the fluorescent labels used could further improve temporal and spatial resolution. However, the range of potential biological applications of the technology in its current state is extensive, and further insights into cell biology are likely to result.

Super-Resolution Light Microscopy: Stimulated Emission Depletion and Ground-State Depletion

Introduction

Super-resolution light microscopy includes a set of techniques that are capable of reaching optical resolution beyond the classical diffraction limit. Diffraction is a fundamental property of light that restricted the resolution of light microscopy for over 300 years. The classical Abbe's law and the Rayleigh criterion state the lateral (The lateral plane is perpendicular to the optical axis. The optical axis is along the direction where light travels.) resolution of a light microscope d_{lat} is limited to:

$$d_{\text{lat}} \approx 0.61\lambda/\text{NA} \quad [1]$$

where λ is the wavelength of light, and NA is the numerical aperture of the microscope objective (Inoue, 1995). Within the visible spectrum (wavelength range from 400 nm to 700 nm), the lateral resolution is thus limited to ~ 170 – 300 nm using high NA oil immersion objectives. The diffraction limit remained a fundamental obstacle of optical microscopy until the invention of a number of 'super-resolution' fluorescence microscopy techniques since the new millennium. The most popular super-resolution techniques include stimulated emission depletion (STED) microscopy (Hell, 2003), scanning ground-state depletion (GSD) microscopy (Bretschneider *et al.*, 2007), photo-activated localization microscopy (PALM) (Betzig *et al.*, 2006), stochastic optical reconstruction microscopy (STORM) (Rust *et al.*, 2006), super-resolution optical fluctuation imaging (SOFI) (Dertinger *et al.*, 2009), and structured illumination microscopy (SIM) (Gustafsson, 2000). This contribution is mainly focused on STED microscopy, which has the following advantages: (1) it achieves super-resolution via a purely physics mechanism and is free from mathematical or numerical processing; (2) unlike SIM, it is in principle capable of reaching unlimited optical resolution (Nonlinear SIM is capable of unlimited optical resolution but lacks practical implementation (Gustafsson, 2005).); (3) unlike stochastic methods, such as PALM/STORM and SOFI, that need to collect thousands of images to obtain super-resolution, STED imaging is performed by point-scanning and can be completed with relatively short time; and (4) it is based on the confocal scheme which enables optical sectioning.

We will also briefly discuss scanning GSD microscopy, a technique very similar to STED microscopy, and ground-state depletion after individual molecule return imaging (GSDIM) (Also referred to as direct STORM or dSTORM (Heilemann *et al.*, 2008)). Scanning GSD microscopy and GSDIM are two very different techniques though based on the same physical mechanism.) (Folling *et al.*, 2008), a variant of STORM. STED and GSD were invented by Dr. Stefan W. Hell, for which he was awarded the 2014 Nobel Prize in Chemistry.

It is worth noting that diffraction is a fundamental property of light which the super-resolution techniques do not eliminate. Instead, all the super-resolution fluorescence microscopy techniques are based on tricks that switch the fluorophores between an on-state, where the fluorophores are fluorescent, and an off-state, where the fluorophores are dark. Two fluorophores are temporally differentiated by placing one of them in the on-state while the other one in the off-state at any given time. A diagram of the low-lying electronic states of a common fluorophore is shown in Figure 1. The ground state S_0 is the stable lowest-energy state, from which the fluorophore can absorb a photon and be excited to the first excited singlet state S_1 . From S_1 , the fluorophore may: (1) spontaneously decay to S_0 and emit fluorescence in a few nanoseconds; (2) undergo an intersystem crossing (ISC) and enter the lowest-lying triplet state T_1 with a long lifetime (depending on the type of dye and the microenvironment, T_1 lifetime ranges from several microseconds to hundreds of milliseconds); and (3) be forced to decay to the ground state S_0 immediately by stimulated emission. STED and GSD are two mechanisms that manipulate the fluorophore states differently. STED uses stimulated emission to quench fluorophores from the on-state S_1 to the off-state S_0 ; whereas GSD uses ISC to deplete fluorophores from the singlet on-states S_0 and S_1 to the dark triplet off-state T_1 .

In the following sections we will briefly overview various super-resolution techniques based on STED and GSD. We will emphasize the physical principles and the technical essentials of various STED and GSD implementations and discuss their pros and cons. We will also give an incomplete review of their numerous applications to the research of cell biology.

Figure 1 Low-lying electronic states of a typical fluorophore. After being excited by a photon from the ground state S_0 to the excited state (on-state) S_1 , the fluorophore has three fates: (1) fluorescence emission; (2) intersystem crossing; and (3) stimulated emission. STED and GSD uses S_0 and T_1 , respectively, as the off-state to switch the fluorophore.

STED and GSD for Super-Resolution: Principle and Technology

STED Microscopy: General Principles

STED microscopy is based on the reversible transitions between the ground state S_0 and first excited singlet state S_1 . The transition $S_0 \rightarrow S_1$ is induced by an excitation laser beam, just like in conventional fluorescence microscopy. The reversal transition $S_1 \rightarrow S_0$ is enforced by stimulated emission, induced by a depletion laser beam at a longer wavelength than the excitation beam, as shown in Figure 2. The depletion wavelength is outside the detection band, therefore stimulated emission is considered as resulting in a dark state. The probability of the reversal transition is controlled by the irradiance of the depletion laser beam: with a sufficiently bright depletion laser beam, the reversal transition dominates, the population at S_1 approaches zero, and the fluorophore is almost always in the off-state. Simply put, a sufficiently bright depletion laser beam will shut off fluorescence.

In confocal fluorescence microscopy, the focal spot of the excitation laser scans over the sample, and the optical resolution is determined by the size of this focal spot. In STED microscopy, the depletion laser beam is spatially modulated to have a doughnut-shaped (Other hollow shapes also work, but the doughnut-shape is most efficient for depletion (Keller *et al.*, 2007).) (hollow with a zero at the center) focal spot and aligned with the excitation laser beam. Assuming two fluorophores, a and b , are located so closely that they are both covered by the excitation focal spot, as shown in Figure 3. At a certain time during STED scanning, fluorophore a sits at the center and is differentiated from fluorophore b at the rim, because fluorophore a is only illuminated by the excitation light and is thus allowed to enter the on-state and emit fluorescence, whereas fluorophore b is also illuminated by the high-irradiance depletion light that effectively keeps it in the off-state S_0 (Figure 3(a)). As a result, at this particular time, only fluorophore a can be detected. When the focal spot moves to the next position, where fluorophore b is at the center and fluorophore a is at the rim (Figure 3(b)), the microscope only detects fluorophore b . Therefore, fluorophores a and b are temporally separated and super-resolution is thus achieved. In other words, the doughnut-shaped focal spot of

Figure 2 The depletion wavelength is chosen to be at the tail of the emission spectrum of the fluorophore, outside the detection band. Spectra of Atto 647 N are used as an example.

the depletion laser prohibits fluorescence emission from the rim of the excitation focal spot and effectively sharpens it, which enhances resolution.

Intuitively, the resolution of STED microscopy depends on how small the central hole of the depletion focal spot is. But the 'smallness' is not measured by the irradiance profile of the hole, which in fact is also subject to the diffraction limit and cannot be very small. Rather, it should be measured by the suppression factor η , defined as the fraction of the fluorescence emission being suppressed. η has a nonlinear dependence on the depletion irradiance I_{dep} : for example, with a pulsed STED configuration (see the next section for a detailed discussion) the suppression factor is

$$\eta(I) \approx 1 - \exp[-\ln 2 (I_{\text{dep}}/I_{\text{sat}})] \quad [2]$$

where I_{sat} is called saturation irradiance. When the depletion irradiance is at I_{sat} , stimulated emission and fluorescence emission are balanced, meaning that there is an equal probability for a fluorophore to be fluorescent or to be depleted (Harke *et al.*, 2008). Therefore, with increasing the depletion irradiance, the suppression factor profile will have a smaller central hole and the optical resolution of STED microscopy d_{STED} will in turn be enhanced:

$$d_{\text{STED}} \approx d_{\text{confocal}} / \sqrt{1 + a \cdot (I_{\text{dep}}/I_{\text{sat}})} \quad [3]$$

where d_{confocal} is the resolution of confocal microscopy, and a is a positive constant (Harke *et al.*, 2008). Figure 4 shows computer-simulated lateral profiles of the focal spots and the suppression factor. The depletion irradiance (red doughnut) has a fixed profile that cannot be controlled. However, when the maximum depletion irradiance I_{max} increases, the central hole of the suppression factor profile (magenta) gets smaller, and the effective focal spot (yellow) used for scanning diminishes, too. It is obvious that indefinitely increasing the

Figure 3 Schematic drawing demonstrating STED principle. Fluorophore a and fluorophore b cannot be resolved by conventional confocal microscopy as they are both covered by the excitation focal spot (green). When aligned with the hollow depletion focal spot (red): (a) at a certain time, fluorophore a is at the center and can emit fluorescence, whereas fluorophore b is at the rim (yellow = red + green, indicating illuminated by both excitation and depletion) and undetectable; (b) when scanning progresses to another time, fluorophore a and b switches positions and only b is detected.

Figure 4 STED microscopy can theoretically reach unlimited resolution. When excitation focal spot (green) is aligned with depletion focal spot (red), the suppression factor profile (magenta) calculated by eqn [2] has a diminishing central hole with increasing depletion power, resulting in diminishing effective focal spot (yellow). The focal spot profiles are lateral and generated by computer simulations.

depletion irradiance can in theory result in unlimited optical resolution.

STED microscopy needs to create a central hole in the depletion beam that can be preserved during light propagation, diffraction, and focusing. The best way to achieve this is to twist the laser beam with a spatial light modulator (SLM) or a vortex phase plate (VPP) (Courtial and O’Holleran, 2007), which can add to the laser beam an angular momentum around the optical axis. Intuitively, a twisted laser beam is like a tornado traveling along its rotation axis. As long as the rotational symmetry is preserved, the light beam will always remain hollow, just like a tornado always preserves a central hole. The microscope objective strongly focuses the depletion beam, and the vector properties of light cannot be neglected in this tight focusing. To ensure the hole has a true zero at the center, the depletion beam must be circularly polarized with the same handedness as the angular momentum induced by spatial modulation (Bokor *et al.*, 2007; Hao *et al.*, 2010).

Pulsed STED Microscopy

Equation [2] indicates that a bright depletion laser beam is crucial to reach a high suppression factor leading to high STED resolution. In pulsed STED microscopy, the depletion light is a fast pulsed laser beam (‘fast’ means with short pulse duration) to reach required irradiance. A schematic drawing of a typical pulsed STED setup is shown in Figure 5. The excitation source must be temporally aligned with the depletion pulse train and therefore must also be pulsed. The excitation source can either be a standalone laser that is triggered by the depletion source, or use a portion of power of the depletion source to pump a nonlinear optics element (e.g., an optical parametric oscillator) to obtain the desired excitation wavelength. An optical delay line or an electronic time-delay circuit can be used to temporally synchronize the depletion and the excitation pulse trains. A depletion pulse follows immediately after an excitation pulse to deplete the fluorophores right after they are

excited. When a femtosecond laser source is used for depletion, the pulses need to be temporally stretched, for example, by a glass rod and a polarization-maintaining (PM) optical fiber as shown in Figure 5, to avoid multiphoton absorption and excessive photobleaching (Dyba and Hell, 2003). However, the depletion pulse duration needs to be much shorter than the fluorophore lifetime to ensure efficient depletion. For a typical fluorescent dye with a 3–5 ns lifetime, the optimal depletion pulse duration is about 0.2–1 ns. The excitation pulse duration needs to be as short as possible.

Pulsed STED microscopy is historically the earliest implementation of STED and it usually produces the best STED images. The primary challenge in pulsed STED microscopy is the availability of the depletion laser source. High power pulsed lasers are quite expensive. In the near-infrared wavelength range, a Ti:Sapphire laser source (e.g., MaiTai HP, Newport, USA) is a very good choice for depletion. In the visible wavelength range, parametric oscillators (Nagerl and Bonhoeffer, 2010), stimulated-Raman-scattering laser sources (Rankin and Hell, 2009), and super-continuum laser sources (Wildanger *et al.*, 2009) can be used for depletion.

Continuous-Wave STED Microscopy

Continuous-wave STED microscopy uses a powerful continuous-wave (CW) laser source for depletion (Willig *et al.*, 2007). The excitation source can be either CW or pulsed. It does not involve the complexity of temporal alignment in pulsed STED microscopy, and a CW laser source is more affordable than a pulsed laser source with similar optical power. The disadvantage of CW STED microscopy is that it requires higher average optical power to reach the same resolution as pulsed STED microscopy. This is obvious when the excitation light is pulsed and eqn [3] holds. The average irradiance of a CW depletion laser source needs to be I_{dep} constantly to reach the resolution d_{STED} ; whereas for a pulsed depletion source the irradiance I_{dep} only lasts for its pulse duration T_w , and the average irradiance

Figure 5 Simplified setup of a typical pulsed STED microscope. A superfast (pulse duration in femtoseconds) laser is used as the depletion source and triggers another pulsed laser source for excitation. A time-delay circuit synchronizes the depletion and the excitation pulse trains. The femtosecond pulses are stretched by a glass rod and a PM fiber to reach pulse duration of several hundred picoseconds. Depletion light is then modified by a VPP to have a hollow cross-section. Glan-laser polarizers and a quarter-waveplate ($\lambda/4$) ensure the light is circularly polarized before being focused by a microscope objective. Fluorescence is collected by the same objective and goes through a confocal pinhole to block out-of-focus light.

is $I_{\text{dep}} T_w R$, where R is the laser repetition rate. Therefore, the average depletion power needed in CW STED microscopy is $(T_w R)^{-1}$ times higher than in pulsed STED microscopy. Compared with using a common Ti:Sapphire laser with a repetition rate of 80 MHz laser and 400 ps pulse duration for depletion, CW STED microscopy needs 30 times higher depletion power to reach the same resolution. Such powerful CW laser sources are often not available, and therefore CW STED microscopes usually reach lower resolution than pulsed ones. Plus, high depletion power induces excessive photobleaching that can permanently destroy the fluorescent dyes. If the excitation is also CW, then excitation and depletion constantly compete against each other, which also results in higher depletion power requirement (Willig *et al.*, 2007).

To summarize, compared with pulse STED microscopy, CW STED microscopy has the advantage of being technically simpler and working with less-expensive laser sources. However, its resolution is usually lower and it suffers from rapid photobleaching.

Time-Gated STED Microscopy

Time-gated detection was invented to enhance the resolution and reduce photobleaching in CW STED microscopy (Vicidomini *et al.*, 2011). In time-gated STED microscopy, the excitation source is pulsed while the depletion source is CW and with relatively low power. Fluorescence detection only takes place within a time-window after a fixed time-delay T_d following each excitation pulse, as shown in Figure 6. The rationale is that, with the low depletion power, the suppression factor η is low and the fluorescence signal from the rim cannot be completely shut off. However, depletion effectively reduces the fluorescence lifetime τ to $\tau_{\text{STED}} < \tau$, because stimulated

Figure 6 Schematic drawing demonstrating the principle of time-gated STED. Fluorophore *a* is located at the rim (yellow) and has a short lifetime $\tau_{\text{STED}} = 0.5$ ns (red shadow) due to depletion; fluorophore *b* is at the center (green) with normal fluorescence lifetime $\tau = 3$ ns (green shadow). Setting a detection window (light blue) with a delay $T_d = 3$ ns resulting in detecting fluorophore *b* only, because $T_d \gg \tau_{\text{STED}}$, and fluorophore *a* is effectively dark.

emission provides an extra pathway for the fluorophore to decay from the first excited state S_1 to the ground state S_0 . The difference in lifetime is exploited by the detection time-window to differentiate fluorophores. The time-delay T_d needs to be carefully chosen. On one hand, T_d should satisfy $T_d \gg \tau_{\text{STED}}$, so that fluoresce at the rim of the focal spot can hardly be detected; on the other hand, T_d should be as short as possible to detect more fluorescence signal at the center. In practice, one needs to work with these two conflicting conditions to find a compromise between the signal level and resolution.

The detection time-window can be either implemented by commercial time-correlated single photon counting (TCSPC) modules or custom-built gating electronics. TCSPC modules

are designed for lifetime microscopy, which are commercially available from PicoQuant or Becker and Hickl, GmbH. With these modules, the arrival time of each photon relative to the excitation pulses can be recorded, and the detection time-window is applied by software (Viciomini *et al.*, 2011). Alternatively, one can simply use a leading edge discriminator with a VETO input (e.g., TD2000 from Fast Comtec, GmbH) to build one's own gating electronics (Wu *et al.*, 2015).

To summarize, time-gated detection enhances resolution by differentiating fluorescence with usual lifetime τ from fluorescence with shortened lifetime τ_{STED} due to depletion. The trade-off is the lowered fluorescence signal level. We only recommend time-gated STED technique to be used for bright samples.

STED in the Axial Direction

The resolution in the axial direction, i.e., the direction where the laser beams travel, is also restricted by the diffraction limit. Similar to performing STED in the lateral direction, one can create a hollow depletion focal spot in the axial direction with SLM or VPP and use it to reach super-resolution (Klar *et al.*, 2000). Using two depletion beams, in which one is laterally hollow and the other axially hollow, super-resolution in three-dimensions (3D) can be achieved (Wildanger *et al.*, 2009). One can take a step further by combining STED with the 4Pi microscopy (Hell and Stelzer, 1992) technique and reach even higher resolution (Schmidt *et al.*, 2008). However, 4Pi-STED microscopy is highly complicated and requires a special sample preparation procedure, which limits its biological applications.

Multicolor STED Microscopy

Multicolor STED microscopy involves finding multiple dyes with well separable excitation and emission spectra. A simple way to perform multicolor STED is to use one depletion laser source to deplete two different dyes, one of which has a long Stokes shift (e.g., long-Stokes-shift dye Chromeo 494 from Active Motif, working together with Ato 647 N). Another way is to deplete two dyes with two different depletion laser lines (Donnert *et al.*, 2007). For example, Atto 647 N and Oregon Green 488 can be depleted at 750 nm and 592 nm, respectively (Wu *et al.*, 2010).

Two-Photon STED Microscopy

Two-photon excitation (2PE) is a widely used technology to image deeply into thick tissues or living animals. Apparently, it is rather straightforward to apply STED to 2PE as the depletion process is no different from single photon excitation (1PE) (Moneron and Hell, 2009). However, the challenge really lies in the fact that 2PE is useful to deep imaging in which the light penetrates into great depth. If the excitation light and the depletion light are at two different wavelengths, they will be scattered differently in the tissue and soon the alignment will be lost and the resolution will diminish. Luckily, it was found that for some organic dyes, at the depletion wavelength there happens to be a decent 2PE probability. Therefore, 2PE-STED

can be implemented with a single wavelength: the excitation laser pulses are very short (in femtoseconds) to induce 2PE, and the depletion laser pulses are greatly stretched to several hundred picoseconds to suppress excited fluorophores (Bianchini *et al.*, 2012). 2PE-STED microscopy faces two additional challenges. First, 2PE photobleaching is much more severe than 1PE (Patterson and Piston, 2000) and 1PE-STED photobleaching is already problematic; therefore 2PE-STED suffers greatly from photobleaching. Secondly, the depletion beam is likely not be able to maintain the hollow shape when penetrating the tissue due to light scattering, unless sophisticated technique such as adaptive optics is employed. Because of these challenges, 2PE-STED microscopy remains elusive and its application in biological research is scarce.

Photobleaching and Resonant Scanning in STED Microscopy

Photobleaching is arguably the biggest problem in STED microscopy. Photobleaching is an irreversible photochemical process that leads to the permanent destruction of the fluorescent dye. The bright depletion beam is the main cause of photobleaching. However, as the depletion pulses are stretched to several hundred picoseconds, they do not directly cause photobleaching (Dyba and Hell, 2003). Figure 7 shows that the primary STED photobleaching pathway is through the low-lying triplet state T_1 . Fluorophores stay in T_1 for a long time and may absorb additional depletion photons to enter the highly unstable high-energy triplet state, T_n , where they are quickly bleached. The long lifetime of T_1 (from microseconds to hundreds of milliseconds) is the key issue as the T_1 population can be accumulating during imaging (Deschenes and Bout, 2002).

Besides common practices such as using anti-fade mounting media and lower laser power, the efforts of reducing STED photobleaching is concentrated on eliminating the triplet-state (T_1) buildup. This can be done with oxygen removal from the microenvironment and using a reducing and oxidizing system (ROXS) as buffer that can quickly recover fluorophores from T_1 (Vogelsang *et al.*, 2008). Another idea is to avoid continuous illumination to give fluorophores enough time in dark for its recovery from T_1 . Triplet-state relaxation (T-Rex) technique is to use low repetition rate pulsed lasers for excitation and

Figure 7 Primary photobleaching pathway in STED microscopy. Fluorophore is excited to the first excited singlet state S_1 , and then undergo ISC to enter the long-lived low-lying triplet state T_1 , where it may absorb a depletion photon to reach the high-energy triplet state T_n and then quickly bleaches.

depletion (Donnert *et al.*, 2007). For example, if the T_1 lifetime is $\sim 1 \mu\text{s}$, T-Rex will use lasers with < 1 MHz repetition rate, so that between consecutive laser pulses the fluorophores can relax from T_1 and go back to the ground state S_0 . This technique is very successful in reducing photobleaching but considerably slows down imaging and is often not practical for fluorophores with very long triplet-state lifetime. The bunched T-Rex technique is a modified version of T-Rex, which bundles 4–5 high repetition rate pulses together and separates the bunches with time periods that allow for T_1 relaxation (Donnert *et al.*, 2009). Another way to relax the triplet-state population is to use fast scanning speed, with which fluorophores are not constantly illuminated since the laser focal spot quickly scans them and then leave (Gardeazabal Rodriguez *et al.*, 2012). We showed that increasing scanning speed with resonant scanners and large field of view can significantly reduce photobleaching without sacrificing the imaging speed (Wu *et al.*, 2014).

Resonant scanning is crucial to implement vide-rate STED imaging, which has reached 28 frames per second (fps) for biological samples (Westphal *et al.*, 2008). Currently, imaging speed of live STED microscopy is not limited by scanning technology but by low acquired fluorescence signal at high frame rate. For bright enough specimens such as fluorescent bead samples, the imaging speed reached as high as 80 fps (Westphal *et al.*, 2007).

Scanning GSD Microscopy and GSDIM

GSD using the low-lying triplet state T_1 as the off-state. It is usually implemented by illuminating the fluorophores with saturated excitation laser power, causing them to be excited and gradually accumulate in the dark T_1 state, based on the long lifetime of T_1 . This process diminishes the S_0 population, which gives this technique its name. The advantage of GSD over STED is that GSD needs much lower depletion irradiance. In STED, depletion competes against spontaneous fluorescence emission, which has lifetime in nanoseconds; in GSD, depletion competes against relaxation from T_1 , which happens with much lower probability than fluorescence emission and has a lifetime in microseconds or even hundreds of milliseconds. Therefore, in GSD one can work with CW depletion laser sources with moderate optical power (Bretschneider *et al.*, 2007; Hell and Kroug, 1995).

There are two categories of methods that employ the GSD mechanism to achieve super-resolution: one is based on point-scanning and we call it scanning GSD microscopy; the other is GSDIM (dSTORM), a variant of PALM/STORM that is based on the wide-field technique using camera. Scanning GSD microscopy is very similar to STED microscopy, just replacing STED with GSD as its depletion mechanism. The advantage of scanning GSD microscopy over STED microscopy is its low need of depletion laser power. However, it has a serious issue of photobleaching due to constant illumination on fluorophores in the T_1 state. The imaging speed is also slower, because the transitions between the off-state (T_1) and the on-state (S_1) are much slower than stimulated emission. Scanning GSD microscopy was demonstrated to be very successful for nitrogen-vacancy centers in diamonds, which do not have the photobleaching problem (Han *et al.*, 2010). However, it is not

widely used in biological research due to the abovementioned disadvantages.

GSDIM is probably the better approach to apply GSD for super-resolution microscopy. After the fluorophores initially receive saturated excitation optical power and enter the dark T_1 state, they will randomly return back to the ground state S_0 , be excited and reenter the on-state S_1 , and release fluorescence due to spontaneous decay. The circle of $S_0 \rightleftharpoons S_1$ will repeat for a number of times before they enter the dark state T_1 again. In GSDIM, the fluorescence emission from the returning fluorophores is recorded by a camera. Although each return is corresponding to a diffraction-limited spot on the camera, the center of the spot can be mathematically determined which indicate the precise location of the fluorophore (Folling *et al.*, 2008). GSDIM is of course very similar to PALM/STORM. The difference is that GSDIM normally uses common organic dyes being switched between the dark triplet states and the fluorescent singlet state, whereas PALM/STORM uses specially engineered photo-switchable dyes or fluorescent proteins. In fact, GSDIM and similar techniques were independently invented by a number of groups and given different names, for example, direct STORM (dSTORM) (Heilemann *et al.*, 2008, 2009). GSDIM is also capable of achieve super-resolution in the axial direction by differentiating focal spots with astigmatism (Huang *et al.*, 2008). The major disadvantage of GSDIM is that it can only work with dyes with large triplet-state yield yet not too vulnerable to triplet-state photobleaching. The common practice is to use buffers that maximize the triplet-state yield of organic dyes (Olivier *et al.*, 2013).

Commercial STED and GSDIM Microscopes

Commercial STED and GSDIM microscopes are provided by Leica Microsystems, GmbH. The latest Leica TCS SP8 confocal microscope can perform STED in multiple channels with three depletion lasers. Leica SR GSD 3D is capable of three-dimensional super-resolution GSDIM imaging.

Biological Applications of STED and GSDIM

Biological Sample Preparation

For most researchers who perform super-resolution imaging, sample preparation is the single most important issue. Without properly prepared biological samples, it is impossible to acquire high quality STED and GSDIM images.

As a rule of thumb, an excellent biological sample for confocal microscopy is also excellent for STED microscopy. An ideal STED sample should be bright, photo-stable, and optically homogenous. In STED microscopy, a great part of fluorescence is suppressed and the image intensity is relatively low. In addition, STED photobleaching is fast due to high depletion power. Therefore, bright and photo-stable fluorescence dyes are highly desired. The choice of STED dyes is based on experiences. Popular STED dyes include Atto 647 N, Oregon Green 488, Chromeo 494, Atto 532, etc. A more complete list of STED dyes covering the entire visible spectrum is given in Reference Muller *et al.* (2012). STED imaging with fluorescent proteins (Willig *et al.*, 2006) is more difficult as

they are less bright and less stable than organic dyes. However, fluorescent proteins have the irreplaceable advantage of being much smaller in size compared to antibodies used for immunolabeling (The size of a typical fluorescent protein is ~ 4 nm. Antibodies are larger, for example, IgG is ~ 10 nm in length (Ehmann *et al.*, 2014). Conventional immunocytochemistry needs both the primary and the secondary antibody to label a biomacromolecule.) and being highly compatible with living cells (For organic dyes to work with live imaging, they need to somehow enter the living cell (e.g., uptake of dye-labeled lipid (Eggeling *et al.*, 2009))). Therefore, STED microscopy using fluorescent proteins can in principle reach higher resolution and is more versatile in live STED imaging than immunocytochemistry. Excellent optical homogeneity implies that the refractive index of the mounting media and immersion oil should be as close as possible to glass. The ProLongTM anti-fade reagent from Life Technologies, Inc. and 2,2'-thiodiethanol (TDE) are widely used as mounting media for STED imaging. Also, cover slips with excellent flatness and a thickness compatible to the microscope objective should be used. Scattering of the excitation and the depletion light by the specimen is more likely to compromise resolution at a higher imaging depth. Therefore, one should prepare the sample so that the area of interest is near the cover slip for best resolution.

Preparing samples for GSDIM is trickier than for STED. In GSDIM, one would want to choose fluorescent dyes with high triplet-state yield and high probability of blinking. Alexa 647, Alexa 532 and Alexa 488 are among the most widely used GSDIM dyes. Samples are often immersed in special buffers, which use reduction and oxidation (redox) agents to manipulate blinking (Steinhauer *et al.*, 2008; Vogelsang *et al.*, 2009). Recent work indicated that GSDIM working with a simple buffer is possible (Olivier *et al.*, 2013).

In all super-resolution techniques, it is important to minimize mechanical drifting and instability for both samples and the optical setup. Ideally, the environment should be free from vibration and temperature fluctuation. It is possible to correct some mechanical drifting with computer algorithms (McGorty *et al.*, 2013), but random vibration and drifting in the optical

components always diminish resolution without an easy remedy.

STED and GSDIM Applied to Biological Research

STED microscopy and GSDIM have been widely used in biological research (Blom and Brisma, 2014; Muller *et al.*, 2012). It is not our intention to provide a comprehensive review of these applications. Instead, we will just briefly overview some of them that we hope can inspire the reader to apply super-resolution fluorescence microscopy to their studies.

Because it works best with thin samples, many successful applications of STED microscopy have been done for isolated organelles and small (thin) cultured cells. An example is given by Figure 8, which shows an early STED image taken by our custom-built STED microscope (Gardeazabal Rodriguez *et al.*, 2012) for cultured neurons where actin was immune-labeled. The STED resolution was ~ 50 nm. Some organelles, such as mitochondria and endosome, are too small for conventional light microscopy to resolve. STED microscopy was used to image voltage-dependent anion channel 1 (VDAC1) and cytochrome c oxidase's subunit 2 (Cox2) clusters in purified mouse cardiac mitochondria, which found that the two proteins had very different cluster-size distributions (Singh *et al.*, 2012). 4Pi-STED microscopy was able to resolve the cristae of mitochondrial inner membrane in intact cultured cells (Schmidt *et al.*, 2009). Isolated early endosomes from PC12 cells were imaged by STED microscopy, which found that synaptic membrane proteins such as synaptophysin and some SNARE proteins form stable microdomains during endocytic trafficking (Geumann *et al.*, 2010). The helix structure of FtsZ, a cytokinetic protein that plays an important role in bacterial division, was revealed by STED microscopy to have an irregular structure (Jennings *et al.*, 2011).

Although it prefers thin samples, STED microscopy has also been extensively used to study large (thick) cells (e.g., cardiomyocytes), tissue sections and dissected samples with thickness up to ~ 100 μ m. STED imaging of membrane endothelial cell markers (e.g., CD146) showed that after acute ischemic cardiac injury fibroblasts can quickly adopt an

Figure 8 Comparison of conventional confocal microscopy (a) and STED microscopy (b) for neurons derived from human iPS cells where actin was immunolabeled with Atto 647 N. (c) and (d) magnify the enlarged boxes in (a) and (b), respectively. In (d), STED shows an axon with a punctuated actin distribution; whereas in the confocal image (c) there are no discrete clusters. Shown are raw images without any processing.

endothelial-cell-like fate (Ubil *et al.*, 2014). It also revealed a doughnut-shaped structure of active zones in larval *Drosophila* neuromuscular junctions, which were immunolabeled by an antibody specifically recognizing the Bruchpilot protein (Kittel *et al.*, 2006). The spatial distribution of histone H3 in neonatal rat ventricular myocytes was visualized by STED microscopy to study the chromatin structure (Mitchell-Jordan *et al.*, 2012). Sub-diffraction-limit imaging of the eGFP-tagged caveolin in Chinese hamster ovary cells (Li *et al.*, 2009) was one of the rare applications of 2PE-STED microscopy to biological samples.

Multicolor fluorescence microscopy and colocalization analysis are widely used in cell biology to study interactions among biomacromolecules. The accuracy of colocalization analysis is limited by the optical resolution of the microscope (Wu *et al.*, 2010). 'Protein *a* is colocalized to protein *b*' actually means that 'we tend to see protein *a* appears within a distance of *D* from protein *b*,' where *D* is at best the optical resolution of the microscope. It is obvious that by reducing this distance *D* from 200–300 nm to 20–60 nm with super-resolution microscopy greatly improve the reliability of colocalization analysis. In Figure 9 we give a concrete example of colocalization analysis in dual-color STED microscopy. We used our custom-built two-color STED microscopy (Wu *et al.*, 2015) to image an isolated cardiomyocyte, where L-type voltage-dependent calcium channel $\alpha 1C$ subunits (Cav1.2, red) and ryanodine

receptors (RyR, green) were independently immunolabeled by Atto 647N and Oregon green 488, respectively. In a small region as shown in Figures 9(c) and (d), the protein-proximity-index (PPI) (Wu *et al.*, 2010) measured by conventional confocal microscopy is 0.79; whereas the STED PPI value drastically drops to 0.38.

Dual-color STED microscopy was used to demonstrate and quantify the colocalization between proliferating cell nuclear antigen (PCNA) and replication protein A (RPA) in a human cell line to study DNA replication (Csereeny *et al.*, 2009). It was also used to quantify the colocalization between hexokinase-I, an important enzyme for phosphorylation, and VDAC in a human cell line. It was found that hexokinase-I has different degrees of colocalization with the three VDAC isoforms (Neumann *et al.*, 2010). At super-resolution, traditional colocalization analysis methods may not work, as the overlap between the signals in two channels greatly diminishes. Blom *et al.* used nearest neighbor analysis together with and dual-color STED microscopy to quantify the spatial density and association of dopamine receptor D1 and Na⁺/K⁺-ATPase in rat dendritic spines (Blom *et al.*, 2012).

STED microscopy has been successfully applied to image living organisms. Dendritic spines in living hippocampal slices from YFP-transgenic mice were visualized by a STED microscope using an optical parametric oscillator pumped

Figure 9 Dual-color STED images taken by our customized-built STED microscope. (a) Overlay of confocal images of an isolated cardiomyocyte where Cav1.2 (red) and RyR (green) were independently labeled. Field of view (FOV) is $32 \times 32 \mu\text{m}$. (b) Overlay of STED image in the same FOV as in A. (c) and (d) Blowup of a region (white square) in (a) and (b) respectively. Images were thresholded and denoised by a 3×3 median filter. The scale bars represent $2 \mu\text{m}$.

by a superfast Ti:Sapphire laser as the depletion source (Nagerl and Bonhoeffer, 2010). In a similar investigation, STED microscopy was able to reach up to 80 μm deep into the living hippocampal slice while maintaining <75 nm optical resolution (Urban *et al.*, 2011). The citrine-tagged (citrine is a variant of YFP that has higher photo-stability) endoplasmic reticulum in living Ptk2 cells was imaged with a 3D-STED microscope using two depletion beams (for the lateral and the axial direction, respectively) (Hein *et al.*, 2008). Video-rate STED microscopy using fast resonant scanners can visualize the living organisms in real time. STED microscopy using a 16 KHz resonant scanner was able to resolve single synaptic vesicles (immunolabeled by Atto 647 N) in cultured rat hippocampal neurons and record their movement at 28 fps (Westphal *et al.*, 2008). Besides fluorescent proteins and organic dyes, 'self-labeling' proteins have also been used for live STED imaging (Fitzpatrick *et al.*, 2009; Schroder *et al.*, 2009). Combined with fluorescence correlation spectroscopy, STED microscopy was able to directly observe the dynamics of fluorescently-labeled membrane lipids in living cultured cells (Eggeling *et al.*, 2009).

GSDIM (dSTORM) is most widely used to image fixed samples. For example, it resolved the distribution of Bruchpilot in active zone cytomatrix (Ehmann *et al.*, 2014) and human leukocyte antigen in natural killer cells (Pageon *et al.*, 2013). Dual-color GSDIM was used to visualize posttranslational tubulin isoforms in MDCK cells (Zink *et al.*, 2012) and to study extracellular vesicle secretion by the astrocyte (Hajj *et al.*, 2013). It was also demonstrated that GSDIM can be used to image living cell culture (Testa *et al.*, 2010). GSDIM (dSTORM) is a stochastic localization-based super-resolution technique that is very similar to PALM/STORM, which is covered elsewhere in this book. Therefore, we are satisfied by giving the above examples for its biological applications and refer the reader to other publications (Henriques *et al.*, 2011; Sengupta *et al.*, 2014) for more thorough reviews.

Conclusion

STED and GSD are two physical mechanisms that can switch common fluorescent molecules between an on-state and an off-state. Fluorescent molecules are temporally separated by this on-off switching, which results in super-resolution. STED microscopy is a point-scanning technology, in which a spatially-modulated focused light is used to sharpen the scanning focal spot to enhance resolution. In GSDIM, fluorescent molecules randomly return from the dominant dark triplet-state to the ground state, from which the single-molecule emission events are separately recorded and the precise location of the fluorescent emitters is numerically determined. STED microscopy has been implemented in various ways, including pulsed STED, CW STED, and time-gated STED. 3D-STED and 4Pi-STED extend super-resolution to three dimensions. 2PE-STED helps penetrate deeper into the sample. Resonant scanning reduces STED photobleaching and realizes video-rate STED imaging. The big family of technologies has enabled STED and GSDIM microscopy to be extensively applied to biological research.

Structured Illumination Microscopy

Introduction

The recent advances in high-throughput genomic and proteomic analysis have helped compile the extensive, but finite list of components that define the function of a cell. A critical task ahead is to integrate this information into molecular assemblies and understand how their structure influences activity in cells (Alberts, 1998). Especially in cell biology, it is of fundamental importance to examine the function and biophysical properties of macromolecular assemblies in conditions closest to their native environment. To this end, fluorescence microscopy is a useful method because it provides molecular specificity through antibody labeling or genetically encoded tags; it is generally efficient at labeling and preserving ultrastructure; and importantly, it is compatible with live cell imaging.

However, fluorescence microscopy was considered until recently to be subject to the hard limit of the light diffraction barrier (Abbe, 1874; Heintzmann and Ficz, 2007, 2013). This theoretical limit was first established by Abbe in 1874 and states that resolution in an optical device is directly proportional to the wavelength of the observation and inversely proportional to the numerical aperture of the objective ($d = \lambda/2NA$; Abbe, 1874; Heintzmann and Ficz, 2007, 2013). In effect, in the best of circumstances, a microscopist can obtain an anisotropic resolution of ~ 250 nm in the in-plane (x - y) direction and ~ 500 nm in the axial (z) direction, when using a fluorescence microscope with a single, high numerical aperture (1.4 NA) objective, and when detecting fluorescence emission around 520 nm. The lack of tools capable of surpassing this optical limit has determined a substantial gap in our knowledge of cell organization, because in cells most macromolecules are organized in assemblies with sizes in the range of few nanometers.

Recently, sub-diffraction fluorescence microscopy methods – often referred to with the less precise but more effective name as super-resolution microscopies – have emerged as powerful tools in biology (Huang *et al.*, 2009; Hell, 2007a; Schermelleh *et al.*, 2010). When compared to conventional fluorescence microscopies (e.g., confocal and widefield microscopy), super-resolution microscopy methods provide an increase in resolving power from 2- to 10-fold (from 125 nm to ~ 10 –20 nm in the x - y plane). Super-resolution methods can surpass the diffraction barrier in two ways: by taking advantage of spatial patterning of the excitation illumination (as in SIM, RESOLFT, and STED) or by detecting single molecules separated in space and time to enable high-resolution localization (as in PALM, STORM, GSD, and related techniques). Since super-resolution methods differ in their principles, resolution capacity, and experimental flexibility, they provide different advantages and disadvantages to the experimental biologist (Huang *et al.*, 2009; Schermelleh *et al.*, 2010; Hell, 2007b).

In this article we present the principles and applications of structured illumination microscopy (SIM). SIM relies on

modulation of the excitation light by spatial patterning to break the diffraction barrier (Gustafsson, 2000, 2008). In its most practical implementation, SIM provides a relatively small resolution gain of a factor of two (Figure 1(a)), yet has the least stringent requirement for fluorophores selection and readily accommodates multiple labeling. This makes SIM the method of choice for multicolor labeling of cellular structures and high-throughput imaging due to its flexibility and relatively ease of sample optimization (Huang *et al.*, 2009; Schermelleh *et al.*, 2008a, 2010).

In the sections below, we first provide an introduction to the principles of linear 3DSIM, which is currently the most common implementation of this technology. We subsequently detail the impact of SIM on different fields of cell biology. We then conclude the article with the most recent developments in SIM imaging (e.g., 2D TIRF-SIM, nonlinear SIM illumination, Bessel-beam SIM, and multifocal SIM), which are leading to better live cell imaging capabilities, to an increase in resolution power and to more effective quantitative analysis.

Principles of SIM

SIM is a method that relies on a modified widefield microscope to collect light from a fluorescently labeled specimen. The defining characteristic of a SIM microscope is the sample illumination: while in a widefield microscope the sample is illuminated homogeneously, in SIM the sample is illuminated with a striped pattern – a ‘spatially structured light illumination.’ The purpose of this pattern is to create 3D interference fringes on the sample, which in turn reveal otherwise unobservable information about the sample fluorophore’s distribution. The net result is comparable to the moiré pattern, a phenomenon that occurs when two structural patterns are superimposed and features of the sample spatial frequencies are revealed that were previously unobservable under a homogeneous illumination pattern (Figure 1(b); Gustafsson *et al.*, 2008; Schermelleh *et al.*, 2008b; Gustafsson, 2000).

In a 3DSIM microscope, the sample illumination with a structured illumination pattern accomplishes two important objectives: (1) it shifts high-frequency sample information not normally observable by the microscope to the range of frequencies the microscope can observe (Figures 1(a) and 1(b)). In turn, these added frequencies lead to an increase in resolution of a factor of two both in the lateral (~ 125 nm) and axial directions (~ 250 nm); (2) it provides 3D optical sectioning by rejecting light from fluorescent objects that are not in the imaging focal plane by axial modulation of the illumination pattern.

Resolution Increase in SIM

To understand the principle of SIM it is useful to introduce the concept of Fourier transform of an image. When a point light

source is detected through a microscope, its image is degraded by the optical apparatus (lenses, objective, etc.). The result is a ‘real space’ blurred image that describes the optical properties of our specific microscope setup, which is referred to as the point spread function (PSF). The Fourier transform of the PSF is named the optical transfer function (OTF) (Figure 1(c); Pawley, 2006; Gustafsson *et al.*, 2008; Gustafsson, 2000; Schermelleh *et al.*, 2010). The OTF as any other image in ‘Fourier space,’ is represented by many sinusoidal curves with different amplitude and frequencies, which correspond to the intensities of each pixel in the ‘real space’ image. In ‘Fourier space,’ the limit of resolution defined by Abbe can be visualized by examining the OTF zone of support, a toroid region including all the spatial frequencies in which the amplitude is above zero – low frequencies lie close to the origin and high frequencies away from the zone (Figure 1(d)).

When we illuminate the sample with a structured illumination pattern we are effectively increasing the observable region in our microscope – the toroid of the OTF zone of support – to higher frequency areas that are normally not detectable by a conventional fluorescence microscope. In the real image those frequencies represent the features of the sample revealed by the moiré pattern (Figure 1(b); Gustafsson *et al.*, 2008; Gustafsson, 2000).

For example, in the case of a single 2D image acquisition in SIM, when we superpose the sample fluorophore distribution with the structured illumination pattern, we obtain the same original image summed with two other images shifted at two different frequency centers (Figures 1(d) and 2(d)). The new image detected is now a mix of information components from the normally observable frequencies of a widefield microscope and the new frequencies originated as in a moiré pattern (Figure 2(d)). The fundamental issue to solve

Convolution with these Fourier components superimposes three copies of the object spectrum into the observable region of the microscope (white arrows). Bottom, left, reconstructed observable region with enhanced support in the direction of pattern. Right, reconstructed observable region using three different orientations of the illumination pattern. Adapted from Fiolka, R., 2014. *Seeing More with Structured Illumination Microscopy*, first ed. Elsevier Inc. Available at: <http://www.ncbi.nlm.nih.gov/pubmed/24974034> (accessed 15.07.14).

at the core of the SIM microscope is to separate and correctly assign these new frequency components on the final ‘reconstructed’ image. This is possible by accumulating pixel intensity information derived from several raw images at each focal plane. In the case of a 2DSIM acquisition scheme, we collect three images, one at each of three lateral grating positions spaced by one-third of the grating’s period. Since translating the pattern by a known amount causes a known change to the phases of the sinusoidal illumination pattern, we refer to three collected images as three phases. The three phases are necessary for separating three information

components, in the same manner as solving three unknowns from three known equations. These three separated components can then be shifted back to where they originate and stitched together. The described procedure extends the resolution in one direction parallel to the image plane. To make the resolution extension more isotropic in the image plane, the procedure is repeated at three different orientations of the grating (Figure 2(c)). By imaging more than three orientations it is possible to obtain a more isotropic increase in the resolution, at the cost of additional images. In a linear 3DSIM setup, imaging three orientations allows

covering an area in Fourier space that is twice as large compared to a conventional microscope, which effectively increases our real image resolution by a factor of two. In the case of 3DSIM there are five information components within each pattern orientation – differently from the three required in 2DSIM – therefore images corresponding to five phases per orientation are collected (Figure 2(c)).

Optical Sectioning in SIM

In a widefield microscope, during image acquisition, the entire sample volume is illuminated every time the focus position is moved in the axial direction. As a consequence, each focal section emits light derived from fluorescent structures part in-focus and part out-of-focus. This type of illumination comes with benefits and costs. On one hand, light collection is very efficient, because all emitted photons from the fluorophores present in our sample are collected, and it is also fast because all the pixels are acquired simultaneously. On the other hand, in this type of illumination low spatial frequency components above and below the x - y plane of the imaged object are poorly detected because of the noise derived by out-of-focus light. This is represented clearly in Fourier space by the toroid shape of the widefield OTF, which has a depression in the middle because of these under-represented frequencies. Ultimately, this determines poor resolution in the axial direction. To improve optical sectioning (and resolution) in widefield, deconvolution algorithms are used to reject out-of-focus light by assigning out-of-focus signal back to the plane where it belongs through analysis of the OTF (Swedlow, 2013; Verdaasdonk *et al.*, 2014; Mertz, 2011).

Differently, in a linear 3DSIM microscope the interference light pattern created on the sample is used to create optical sectioning. Since light derived from in-plane structures is modulated by the interference pattern much more strongly than out-of-focus structures in our sample, we can compare several raw images of our sample illuminated with an interference light pattern and combine it with a computational algorithm to reject out-of-focus light. Because the diffraction pattern is also axially modulated the frequencies under-represented in widefield are better observed (Figure 1(d)). It is important to mention that the way optical sectioning is achieved in 3DSIM is different from another similar named technology optical-sectioning SIM (Mertz, 2011; Langhorst *et al.*, 2009). In this case, there is no axial modulation of the interference pattern, but only in-plane (Mertz, 2011; Langhorst *et al.*, 2009).

For a more detailed analysis of the principle of SIM the reader can refer to the initial theoretical contributions and the papers detailing the experimental proof of principles (Gustafsson *et al.*, 2008; Heintzmann *et al.*, 2002; Gustafsson, 2000).

Microscope Hardware, Software, and Data Acquisition

In this section we describe the main optical engineering elements and the fundamental steps of image acquisition and processing of a linear 3DSIM microscope.

Generation of the Structured Illumination Pattern

In a SIM microscope, the illumination is provided by a laser light source and delivered collimated by a fiber to the diffraction grating. This latter element is considered as the core of the SIM setup: its purpose is to generate the diffraction pattern that is then projected onto the back focal plane of the objective (Figure 2(a)). Of all the rays generated by the diffraction grating, the back aperture of the objective collects only three diffraction orders. These beam orders (-1 , 0 , $+1$, the undiffracted, and ± 1 diffraction maxima) interfere on the sample plane to produce the sinusoidal pattern that has both lateral and axial structure (Figure 2(b)). In linear 2DSIM, the 0th order is blocked, resulting in a purely lateral sinusoidal pattern with no axial structure, while in 3DSIM the 0th is unblocked. Altogether, this process can be visualized as if it produces a reduced image of the diffraction grating on the objective sample plane (Gustafsson *et al.*, 2008; Fiolka, 2014).

During SIM imaging of one plane, the grating is translated – to obtain five image phases – and rotated – to obtain three angles – for a total of 15 raw images. These raw images are essential to separate the different information components contained in the summed image, similar to the moiré pattern (Figure 2(c)). In one of the first implementation of 3DSIM a piezoelectric positioner moved the diffraction grating, but this device is relatively slow and requires long settling times (Dobbie *et al.*, 2011). In addition, a rotational stage is used to rotate the grating and the positioner for imaging the different angles. Recently, a spatial light modulator (SLM) has substituted these three elements (Kner *et al.*, 2009; Shao *et al.*, 2011). The SLM makes use of liquid crystals to generate the diffraction pattern very rapidly and reduce the need for moving mechanical parts, which in turn can introduce mechanical drift. While the illumination portion of the 3DSIM microscope is relatively complex, the detection path is very similar to any other widefield microscope and will not be discussed here in detail.

Image Preprocessing

As mentioned above, during a 3DSIM experiment a relatively high number of raw images per z stack are acquired – 5 images per each grating angle rotation for a total of 15 images for z slice. Because the images of the three angle rotations contribute equally to the final reconstructed image, it is then useful to compensate for sample photobleaching occurring during acquisition between different angles. While this correction might be already hardcoded in the reconstruction procedure, in the case of samples particularly sensitive to photobleaching ($>10\%$ between angle rotations), it might be necessary to adjust the exposure times for each angle in the acquisition scheme to obtain the best reconstruction quality. A step of background subtraction is also generally applied to the image stack before further processing, which takes care of homogeneous noise derived from sample preparation.

Band Separation/Unmixing

Once all the images derived from phase shifts and angle rotations are obtained, the SIM image stack now contains

high-frequency information summed with conventional image (Figure 2(d)). To obtain the final high-resolution 'reconstructed' image it is necessary to first separate these information components. This procedure – band separation/unmixing – is done by solving a series of linear equations. Either three (in 2D) or five independent (3D) images at different phases (3D) are necessary to separate the bands. This in turn determines the number of raw images acquired (9 or 15 for three rotation acquisitions) per individual z plane in the stack (Gustafsson *et al.*, 2008; Carlton, 2008; Righolt *et al.*, 2013, 2014). The next step is to estimate a scale factor that describes the contrast of each high-resolution band compared with the conventional band, a procedure that is referred to as parameter fitting (Figure 2(d)) and takes advantage of the overlapping region between the bands.

Inverse Wiener Filtering and Apodization

After band separation and parameter fitting, the bands are assigned to the correct locations in Fourier space and a generalized Wiener filter is applied. This is done by dividing the separate bands of the image in Fourier space by the OTF at the corresponding frequencies plus a constant (the Wiener filter). This constant is important because it prevents noise being amplified especially near the high-resolution region where the OTF value is low. The value of this Wiener constant is empirically determined: when it is set too high, it can have the effect of blurring the image by removing the fine details present at high spatial frequencies, while if it is too low, then low-frequency noise and honeycomb pattern can appear in the reconstructed image (Righolt *et al.*, 2013, 2014).

In the reconstruction algorithm, an apodization filter is applied to reduce the sharp transition to zero of frequencies near the edge of the observable region. The apodization step reduces ringing effects and ultimately improves the dynamic range of the reconstructed image. Since the parameters of the apodization function are empirically determined, there is an interest by several groups to better optimize their values to increase the robustness of the SIM processing algorithm (Righolt *et al.*, 2013, 2014). At last, after filtering the different bands corresponding to the high and low spatial frequencies the images are then assembled into a volume that has twice the resolution.

Imaging Artifacts: Causes and Manifestations

In this section we discuss the most common causes of artifacts and their manifestations in a linear 3DSIM experiment. While in certain cases the presence of some stereotypic image features can point to errors in particular steps during image acquisition and processing, it is important to underscore that multiple hardware and processing problems can cause a similar artifact in the final image.

Image Drift

In a 3DSIM experiment, sample movement is one of the most common causes of failure in obtaining a reconstructed image. The movement can be caused by the biological phenomenon

of interest, as in a live cell imaging experiment, or by mechanical or thermal drift. The SIM microscope has a certain tolerance to sample movement, which is directly related to its resolution. As a general rule, in a linear 3DSIM the fluorescence structure that is being imaged should not move a distance larger than the microscope resolution (~ 100 nm) during a single stack acquisition (Shao *et al.*, 2011; Kner *et al.*, 2009). This tolerance can be even larger in particular circumstances as discussed below (see section on live SIM). The manifestation of drift in the reconstructed image is the formation of a striped pattern and/or the formation of a deformed object due to the incorrect position assignment of the different sidebands.

Refractive Index Mismatch

When imaging deep into tissues or in an area in the cell where there is a local change in refractive index (i.e., around membrane regions), there is a significant scattering of light that can cause a reduction of the image signal to noise. The scattering can be accentuated by a mismatch of the refractive index between our sample, the imaging medium, and objective immersion material. This is a general problem that affects all microscopy techniques, but it has a more pronounced effect in widefield-based microscopes as SIM, where not only the fluorescence emission can be significantly altered by illumination from other focal planes, but also the quality of the SIM illumination pattern can be affected (Ball *et al.*, 2012; Gao *et al.*, 2014). In practice, in most experiments the refractive index mismatch becomes relevant only when imaging structures a few micrometers away from the coverslip. When present, refractive index mismatch results in the formation of an asymmetrical psf and can be easily detected by looking at x/z or y/z sections of a bead embedded in our sample and subsequently corrected by using oil of matching refractive index (Wallace *et al.*, 2001; Ball *et al.*, 2012).

Low Signal to Noise

The imaging of a fluorescent sample with high signal-to-noise is desirable in many types of microscopy, and SIM is no exception, but it is not always an option. When dealing with poor signal to noise it is important to understand its origin: it can be an inherent property of our sample – which is a complex problem to solve – or alternatively can be a result of the degradation of the sample modulation contrast in the interference pattern. This type of signal degradation can be caused, for example, by hardware misalignment or by light scattering present when imaging samples away from the coverslip. The problem of low modulation contrast has limited the application of linear 3DSIM to tissue specimens to depths not larger than 10–15 μm . As we will discuss in the Section Recent Developments, new SIM strategies are aimed at imaging samples at larger depths. When imaging samples with low signal to noise, the overall effect is generally a catastrophic failure of the reconstruction.

Pixel Negative Values

When imperfectly reconstructed, SIM images can show negative pixel values, especially at the edge of bright objects.

The negative pixel values are introduced by the inherent nature of complex number mathematics in reciprocal Fourier space, and are introduced when excessive low-frequency filtering is applied to the image. The presence of negative pixel values is a potential concern when quantitation of the image intensities is required (Righolt *et al.*, 2013, 2014). However, the problem of negative pixel values is generally readily addressed by an accurate assignment of the reconstruction algorithm parameters.

In conclusion, a quality control of the reconstructed SIM image is necessary to prevent or eliminate sources of artifacts. It is critical to carefully inspect the raw images and look in detail at the log files, which contain information on each step of the processing of the SIM image. The raw images should be examined for the presence of phase shifts, intensity differences between angles, as well as overall image modulation contrast. These elements give us an idea of the overall quality of our sample and its compatibility with SIM imaging. In the reconstructed image, the Fourier transform of the 3D volume should be analyzed for symmetry and homogeneity, which is lost due to incorrect sidebands assignment. Recently, an excellent user-friendly image j-based plug-in has been developed by Graeme Ball and Lothar Schermelleh at University of Oxford (See Relevant Website Section). SIM check is compatible with different formats of commercially available microscopes and provides an efficient way to assess the quality of the reconstructed SIM image.

Applications

Unlike other super-resolution techniques, SIM does not require any specialized fluorescent dyes or genetically encoded proteins and easily accommodates multicolor imaging. In addition the sample preparation is not different from any other conventional fluorescence microscopy technique (Ball *et al.*, 2012; Dobbie *et al.*, 2011). Altogether, these qualities of SIM microscopy greatly facilitate the direct transition to a super-resolution method from confocal or widefield microscopy.

Initially, the vast majority of SIM applications was mainly intended as proof of principle of the hardware and, as such, was focused on structures densely labeled like fluorescent beads, actin, or microtubule structures. Since the introduction of turn-key 3DSIM microscopes from several manufacturers (e.g., General Electric, Zeiss, and Nikon), we are now garnering a large amount of novel information in the recent literature on a variety of cellular structures. In this section we describe some of the most interesting applications with an emphasis on the experimental work that went beyond a purely descriptive analysis.

Nuclear, Chromatin Topography, and DNA-Protein Assemblies

One of the very first biological applications of SIM analyzed different protein components and DNA in the context of the nuclear pore complex (120 MDa in vertebrates) in mammalian tissue culture cells (Schermelleh *et al.*, 2008b). This work provided the first evidence of a zone of exclusion of chromatin from regions where nuclear pore complex (NPC) are positioned at the nuclear membrane. Recent studies have aimed at

further expanding these findings by combining 3DSIM with fluorescence *in situ* hybridization (FISH) to map in detail chromatin domains, areas of chromosomal interactions, and the positions of individual genes within specific protein assemblies (Markaki *et al.*, 2010, 2012). More recently, 3DSIM has been employed to characterize the number of foci of DNA replication (Baddeley *et al.*, 2010). By taking advantage of the increased axial resolution, 3DSIM allowed a more accurate and statistically significant quantitation ('quantification' is better) of the total number of foci in mouse cells compared to conventional fluorescence imaging. 3DSIM has also been successfully applied to examine the organization of chromosome structures as the synaptonemal complex both in *Caenorhabditis elegans* and maize chromosomes (Carlton, 2008). As a whole, the nuclear architecture studies highlight the power of 3DSIM for multicolor imaging and its flexibility to study both proteins and DNA when it is possible to use fluorescent probes as in FISH.

Centrosome Structure and Protein Domain Mapping

The centrosome – the major microtubule organizing center in animal cells – is an organelle whose dimensions are ~200 nm in diameter per 200 nm to several microns in length depending on the species. Its size at the boundary of the resolution limit makes it an ideal organelle for SIM imaging. The centrosome is composed of the centriole, a ninefold symmetrical core, surrounded by the pericentriolar material (PCM). While the centriole structure has been extensively studied by electron microscopy (EM), for many years the understanding of the architecture of the PCM has been a particularly difficult problem to tackle. The PCM contains numerous large coiled-coil containing proteins, which are very difficult to purify, and it appears as a relative homogeneous electron dense cloud under the electron microscope. Recent systematic SIM studies revealed the existence of multiple layers in the PCM by establishing the position and orientation of several proteins critical for centrosome maturation in a systematic manner (Lawo *et al.*, 2012; Mennella *et al.*, 2012; Sonnen *et al.*, 2013; Fu and Glover, 2012). Unexpectedly, SIM analysis showed that some of these components display distinctive distributions: some are organized as apparent molecular fibers or toroids extending away from the centriole wall (pericentrin/PLP, Cep152/Asl), while others are organized in a matrix (Cep192/Spd-2, Cep215/Cnn, and γ tubulin; Figures 3 and 4).

In addition to changing our understanding of the structural organization of the PCM, SIM analysis allowed for the construction of a positional map of specific components of the PCM using probes against different protein domains of the PCM coiled-coil proteins. These experiments demonstrated that one of the components of the PCM, pericentrin/PLP, adopts an extended conformation and that the molecules are anchored at the centriole wall region through their C-terminal PACT domain, while the N-terminal projects outwards the periphery. In addition, a cell cycle analysis of pericentrin-like protein (PLP) molecules showed a two-state PLP structure (open vs. closed) that correlates with different states during the centriole duplication pathway (Mennella *et al.*, 2013). Overall these experiments showed the potential of super-resolution

Figure 3 SIM and molecular architecture analysis. 3DSIM reveals the molecular architecture of pericentrin-like protein (PLP). (a) Amino-acid map of *Drosophila* PLP isoforms predicted from the Flybase database. (b) 2D projections of the average aligned volumes obtained either from S2 cells stained with rabbit anti-PLP MD primary antibodies (amino acids 1805–2137, anti-rabbit Alexa 488) or anti-PLP NTD primary antibodies (amino acids 1–381, anti-rabbit Alexa 488). S2 cells expressing eGFP-PACT were co-stained with mouse anti-eGFP monoclonal antibody (anti-mouse Alexa 488). Nonmuscle myosin II isoforms coassemble in living cells. *Current Biology*: CB 24 (10), 1160–1166. Available at: <http://www.ncbi.nlm.nih.gov/pubmed/24814144> (accessed 16.07.14).

methods to study not only the ensemble distribution of molecules, but also the orientation of individual molecules, and their distinct large-scale conformational states, all in the context of cells.

Ciliogenesis and Structural Analysis of Organelles

3DSIM has been applied with impressive results to the analysis of the pathway of centriole duplication during ciliogenesis in epithelia from mouse trachea cells (Zhao *et al.*, 2013; Jord *et al.*, 2014). In these works, 3DSIM imaging allowed the identification of distinct stages of this process by detailing the specific protein composition and architecture of deuterosomes, while simultaneously allowing overall measurements of size and orientation of this relatively uncharacterized organelle. This is a paradigmatic example of how 3DSIM can

complement, enrich, and partially substitute the information derived by EM imaging, because it requires less time in terms of sample processing and optimization.

Cytoskeleton Structure and Motor Proteins Organization

The high density of labeling of cytoskeletal structures makes them a very attractive target for SIM imaging and super-resolution microscopy methods in general (Engel, 2014). The major advantage of using SIM for such biological application is to achieve a more effective separation of individual cytoskeletal elements, which in turn allows a better quantitation of the number of filaments (Miao *et al.*, 2013), their structural nature ((Brown *et al.*, 2011), and overall dynamics (Kner *et al.*, 2009; Komis *et al.*, 2014; Fiolka, 2014). Recently, the formation of assemblies composed of different isoforms of

myosin II in cells has been demonstrated for the first time (Beach *et al.*, 2014). This was possible by taking advantage of the filamentous structure of myosin II and by labeling opposite ends of the heteromeric complexes that are separated by ~ 300 nm. This application highlights, similarly to the studies of the PCM, how SIM can be used to analyze the detailed organization of molecular assemblies in the cellular context. In a thorough analysis of the final steps of cell division in HeLa cells, SIM was critical for shedding light on the asymmetrical and dynamic organization of two machineries involved in complementary steps during abscission (Elia *et al.*, 2011, 2013; Guizetti *et al.*, 2011). In this work, SIM was used in combination with conventional live cell imaging and electron tomography reconstructions to define the different contribution of the ESCRT-III complex, which is required for cortical constriction, and the severing enzyme spastin, which is involved in microtubule bundle depolymerization in the process of abscission (Elia *et al.*, 2011, 2013; Guizetti *et al.*, 2011).

Bacteria Structural and Functional Organization

In a recent paper from Lesterlin *et al.* (2014), SIM was used to examine the organization and dynamics of bundles of Rec A, a protein involved in sister pair chromatid homology recombination repair in *Escherichia coli*. In this work, SIM imaging contributed to a better understanding of Rec A filament architecture and dynamics and their relationship to other components of the recombination machinery. By showing the existence of different populations of Rec A filaments, one stable and one highly dynamic, this work ultimately provided insights into the mechanism of homology repair in prokaryotes (Lesterlin *et al.*, 2014). Other studies also examined the role of filamentous structures in bacteria that are part of their shape formation machinery (as MreB filaments) (Olshausen *et al.*, 2013), the cellular architecture of the machinery involved in septum formation in *Bacillus subtilis* (Eswaramoorthy *et al.*, 2011), and the filamentous organization of tubulin and actin homologues involved in formation

of the z ring critical for cell division of bacteria (Coltharp and Xiao, 2012; Szwedziak *et al.*, 2012; Strauss *et al.*, 2012).

Recent Developments

Live SIM

When compared to other super-resolution microscopies as STORM–PALM, SIM has the considerable advantage of requiring relatively few raw images (5000–10 000 frames per STORM/PALM image, Winter and Shroff, 2014). SIM microscopy requires low illumination intensity compared to methods like STED (Klar *et al.*, 2000; Huang, 2010; Hell, 2009), which in turn allows minimal photobleaching and longer imaging time series. Moreover, because linear SIM does not rely on stimulated emission, it causes less phototoxicity and photodamage (Rego *et al.*, 2012). These properties suggest that SIM microscopy might be in the long run the super-resolution method best suited to perform live cell imaging experiments with long time series and large field of views.

However, with few exceptions SIM has been thus far applied to image samples chemically fixed and processed for immunostaining. The fast time scale of most biological processes, which are beyond the reach of linear SIM, has largely determined this limitation. To address this issue, in recent years hardware and software modifications have been implemented that significantly speed up image acquisition. These schemes improve the speed of interference pattern scanning (SLM), allow ultralow confined sample illumination (2D TIRF-SIM, Bessel beam SIM) or developed altogether different illumination schemes (multifocal SIM).

In the SIM implementation of Kner *et al.* SLMs were introduced for the first time. SLMs generate diffraction patterns with precise phase and intensities by varying the refractive properties of its liquid crystals. This allows rapid pattern switching and enables very fast acquisition rates (Table 1; Kner *et al.*, 2009; Fiolka *et al.*, 2012; Fiolka, 2014). This SIM microscope also implemented a TIRF illumination system which (1) improves the signal to noise, which allow further reduction of the illumination exposure time and (2) reduces the number of raw images to nine per z stack, because in a 2DTIRF scheme only three phase images per angle are necessary (Gustafsson *et al.*, 2008; Kner *et al.*, 2009). This strategy has been successfully applied to the live cell imaging of microtubules and kinesin motors (Kner *et al.*, 2009) and later to the study of the actin

cytoskeleton at the leading edge in the absence of cofilin (Vitriol *et al.*, 2013).

In a subsequent implementation, a new generation of faster SLM and a different acquisition scheme allowed impressive live imaging results of mitochondria dynamics in Hela cells (Table 1; Shao *et al.*, 2011). This strategy is based on the acquisition of first phases and angles for each z plane, which further reduces the overall acquisition time. As previously discussed, for effective live cell imaging in SIM mode, the fluorescence structure of interest should move slower than the speed of image volume acquisition – ~100 nm in a single stack. Interestingly, individual z planes did not suffer from motion artifacts of different planes due to the depth of focus of 400 nm in a 3DSIM experiment (Shao *et al.*, 2011).

In a scheme substantially different from linear 3DSIM, Schroff *et al.* implemented a multifocal live cell imaging SIM strategy that takes advantage of simultaneous point-based illumination pattern at multiple focal points and a final deconvolution step (York *et al.*, 2013, 2012). This combined approach produces an effect similar to a pinhole in a confocal microscope and it is capable of reaching resolution comparable to a linear 3DSIM (145 nm lateral and 350 nm axial). The main advantage of this approach is the very fast frame rate compared to other super-resolution microscopy techniques (two color 3 μm stack in 1.2 s (Winter and Shroff, 2014; York *et al.*, 2013, 2012)). This method has been applied successfully to image a wide range of processes as mitochondria, peroxisome, and ER dynamics (Figure 5; York *et al.*, 2013).

In another very recent implementation, the structured illumination pattern of SIM is combined with a confined illumination excitation into a defined focal plane achieved by planar bessel beam illumination (BBSIM, Gao *et al.*, 2012). While in BBSIM there is only a modest increase in resolution (Table 1), this scheme increases contrast and signal-to-noise and reduce phototoxicity, qualities particularly advantageous when imaging thick samples as in multicellular organisms. A direct comparison between SIM and BB3DSIM shows that the planar illumination introduced by Bessel beams increases image quality in thick samples at depths over 15 μm , which are generally outside the reach of SIM, because of low modulation contrast and increased sensitivity to aberration (Figure 6). Another important advantage of this method is that it determines an increase in the number of sections imaged per second to 10–27 planes sec^{-1} . This methodology has achieved impressive results in imaging individual chromosomes for karyotyping in mitosis, macropinocytosis

Table 1 Comparison of the properties of structured illumination microscopy methods for live cell imaging

Sim method	Publication	Resolution x/y/z (nm)	Depth of view (μm)	Frame rate (Hz)	Time points	Field of view (μm)	Power (W cm^{-2})
2DTIRF SIM	Kner <i>et al.</i> (2009)	112/112	0.1	3.7–11	480	32 $\times$ 32	5–10
3DSIM	Shao <i>et al.</i> (2011)	120/120/360	<15	0.2	50	200 $\times$ 200	5.5
SSIM	Rego <i>et al.</i> (2012)	40/40	0.1	NA	1	115 $\times$ 115	1–10
MMSIM	York <i>et al.</i> (2013)	145/145/356	>15	100 (2D); 5–10 (3D)	>100 (2D); 17 (3D)	6.5 $\times$ 3.8 (2D); 71 $\times$ 45 (3D)	5–50
BBSIM	Gao <i>et al.</i> (2012)	180/230/350	>15	10–20	50–100	Variable	NA

Note: Most parameters are dependent on the sample type.

Figure 5 Multifocal SIM enables high-speed two-color super-resolution imaging. Live MRL-TR transformed human lung fibroblasts expressing TFAM-GFP (green) and Tom20-mCherry (magenta) were imaged in multifocal SIM (a–c) and spinning-disk confocal (d–f). Maximum-intensity projections (xy) of 3-μm-thick volumes are shown in (a), (d) with subregions (white arrows) at indicated time points in higher magnification (inset). Scale bars, 10 μm and 1 μm (insets). Higher magnification of mitochondria is shown in (b), (c), (e), (f) highlighted by white rectangles from insets in (a), (d). Scale bars, 0.5 μm. Axial (zy) views of ~270-nm-thick slices (yellow lines, (a), (d)) are shown in (c), (f). White arrowheads indicate TFAM enclosed by Tom20 in instant SIM. Scale bars, 1 μm.

and actin cytoskeleton dynamics, and more thick samples as *C. elegans* embryos (Gao *et al.*, 2012, 2014).

Another way to reduce the overall acquisition time is to find ways to reduce the exposure time by requiring less signals: this can be achieved with denoising algorithms that are capable of reducing the background noise introduced by digital processing. Denoising algorithms take advantage of the different properties of correlation between adjacent pixels between signal and noise to identify and reduce the impact on noise on raw images. As a consequence, a reduced exposure to laser light reduces phototoxicity and photobleaching thus allowing longer imaging experiments without compromising the integrity of the sample. So far these algorithms have been applied to widefield images, but efforts are under way to analyze SIM data sets (Buades *et al.*, 2005). It is likely that in the near future, the combination of fast and novel illumination patterning and noise reduction algorithms will allow the application of live SIM imaging to a large range of biological processes happening on faster time scales than $< 100 \text{ nm sec}^{-1}$.

Nonlinear SIM

In nonlinear structure illumination (NLSIM) experiments, resolution higher than linear 3DSIM can be derived from harmonics generated by nonlinear effects of fluorophore activation and emission. These higher order harmonics are

obtained either when high-energy light pulse is shined on the sample (Heintzmann *et al.*, 2002) or when photo-switchable fluorophores are used (Rego *et al.*, 2012). In principle, this method can achieve infinite resolution, in practice, the high laser intensities required to obtain nonlinear responses from the fluorophores decrease the sample photostability, leading to a rapid degradation of the signal to noise. This in turn limits the number of effective harmonics from which to derive the high-resolution information (Rego *et al.*, 2012). Experimentally, NLSIM has achieved resolution in the order of 40–50 nm in a 2D TIRF setup. By using the photoactivatable protein Dronpa NLSIM can achieve harmonics with significantly lower light intensities and it has been employed to study cellular structures as microtubule and actin. Unfortunately, the application of this strategy for live cell imaging or to analyze 3D volumes will require the development of photoactivatable proteins that are more photostable and that can sustain a large number of cycles with the same photon output (Rego *et al.*, 2012).

SIM Image Alignment and Averaging

As described in previous sections, SIM experiments can provide quantitative positional information, all inside the cell. The distribution of molecular assemblies, but also their domain localization and molecular orientation within individual molecules can be obtained providing an unprecedented

Figure 6 Comparison of Bessel plane SR-SIM with 3DSIM in densely fluorescent or thick specimens. (a) Three orthogonal maximum-intensity projections of chromosomes in a live LLC-PK1 cell in anaphase, as seen by Bessel plane SR-SIM. (b) Similar views in another live LLC-PK1 cell in anaphase, as seen by widefield 3D SR-SIM. (c) Lateral (left) and axial (right) maximum-intensity-projection views of a living early-stage *C. elegans* embryo, as seen by Bessel plane SR-SIM. (d) Similar views in another living *C. elegans* embryo, as seen by widefield 3D SR-SIM. Scale bars: 2 mm in (a) and (b); 5 mm in (c) and (d). Reproduced from Gao, L., Shao, L., Higgins, C.D., *et al.*, 2012. Noninvasive imaging beyond the diffraction limit of 3D dynamics in thickly fluorescent specimens. *Cell* 151 (6), 1370–1385. Available at: <http://www.pubmedcentral.nih.gov/articlerender.fcgi?artid=3615549&tool=pmcentrez&rendertype=abstract> (accessed 10.07.14).

snapshot of the organization of supra-molecular complexes in cells (Lawo *et al.*, 2012; Mennella *et al.*, 2012; Beach *et al.*, 2014).

In order to fully extract the quantitative information from 3DSIM – and other super-resolution – images, rather than merely showing anecdotal examples, it is useful to develop image processing and analysis tools to derive image averages of cellular structures. The derivation of an average

image volume enhances the similarities between individual examples, largely deemphasizes stochastic variability and deformation introduced by fixation, while it still allows an analysis of the individual volume variance and heterogeneity (Mennella *et al.*, 2012, 2013).

Toward this goal, recently cryo-tomographic analyses have been applied for the first time in SIM imaging. In this method 3D sub-volumes are aligned by translating, tilting, and

in-plane rotating the volumes to a reference by cross-correlation of voxel intensities. One major advantage of this method is that it provides outstanding quantitative metrics of the spatial distribution of cellular components with error in the range of a few nanometers (up to 2.5 nm, personal communication). This in turn favors a precise and unambiguous protein domain position assignment. It is important to mention that high measurement precision does not necessarily mean high accuracy in determining macromolecules position. The distance of the antigen from the fluorophore (Ries *et al.*, 2012) still contributes to the overall accuracy of our measurement.

Fluorescence Correlation Spectroscopy: A Tool for Measuring Dynamic and Equilibrium Properties of Molecules in Cells

EL Elson, Washington University School of Medicine, St. Louis, MO, USA

© 2016 Elsevier Inc. All rights reserved.

Glossary

Observation volume or area The open volume (or area for two-dimensional systems) that is illuminated by the

excitation laser and from which fluorescence is detected. The observation volume is typically limited by a confocal aperture in the microscope optical system.

Introduction

To understand dynamic molecular processes of metabolism and regulation at the cellular level it is necessary to determine how specific molecules move and interact on the surfaces and within living cells. To accomplish this task requires methods that have the following characteristics:

1. Chemical selectivity – the ability to measure the concentrations of specified molecules present at low concentration within an environment, for example, cytoplasm, that contains high concentrations of many other kinds of molecules
2. A wide dynamic range from <microseconds to >minutes
3. Relatively short time required for the measurements (seconds)
4. High spatial resolution to enable measurements within dimensions <1 μm
5. Sensitivity, even down to the single molecule level
6. Lack of toxicity and interference with normal cell function
7. Ability to localize the measurement within identifiable cell structures and features
8. Applicability to a range of concentrations from nM to μM .

These specifications suggest the use of fluorescence, which has the required rapidity of measurement, sensitivity, and selectivity, and, when based on a confocal fluorescence microscope, the spatial resolution and ability to localize the measurement relative to cell structures. Furthermore, when used judiciously, fluorescence of labeled molecules can be measured with little damage to living cells. Two closely related and complementary methods, fluorescence correlation spectroscopy (FCS) and fluorescence photobleaching recovery (FPR, also known as fluorescence recovery after photobleaching, FRAP) take advantage of these properties of fluorescence to measure rates of molecular transport, for example, diffusion and convection, and of chemical reaction over a wide dynamic range of concentrations and time in living cells.

FCS was introduced in 1972 (Magde *et al.*, 1972). The history of its origins and development have been related from the perspectives of the two groups that first demonstrated the feasibility of using fluorescence fluctuations to measure translational diffusion and chemical kinetics (Elson, 2013a,b) and rotational motion (Rigler, 2009). FCS remained a specialized subject of study for a number of years until technological advances enabled more rapid and robust measurements and this in turn led to the production of

commercial instruments by a number of companies and widespread use of FCS in many laboratories. Important improvements in FCS measurements resulted from using confocal microscopy to limit the volume from which fluorescence is detected (Koppel *et al.*, 1976; Rigler *et al.*, 1993) and which allowed single molecule detection (Mets and Rigler, 1994; Rigler, 2009). Improvements in microscope technology (infinity-corrected optics) and stability of fluorophores and computation of correlation functions (Schatzel *et al.*, 1988) also were important contributions. Improvements in microscopy minimized the detection volume thereby diminishing interfering background fluorescence while increasing the detected number of photons emitted per fluorophore.

Basic Concepts and Theory

Correlation of Fluctuations of Concentration and Fluorescence

Most conventional methods to measure chemical rate constants determine their values by perturbing the molecular system from its equilibrium state, for example, by a temperature jump that displaces the system from equilibrium, and then observing the rate of relaxation back to equilibrium (Eigen and De Maeyer, 1963). Similarly, conventional measurements of diffusion are typically carried out by observing the dissipation of a concentration gradient that has been created in the system by the experimenter (Tanford, 1961). In contrast, FCS measures these rates without perturbing systems that remain in equilibrium or nonequilibrium steady states during the measurement. In an open volume of a chemical system defined by a focused laser beam, the numbers of molecules of the system components continually fluctuate due either to their diffusing into and out of the volume or to their participating in chemical reactions. The fluctuation of the concentration of chemical component, j , at position r and time t is $\delta C_j(r,t) = C_j(r,t) - \langle C_j \rangle$ where $\langle C_j \rangle$ is the equilibrium (or nonequilibrium) steady state value of the concentration. The concentration fluctuations, $\delta C_j(r,t)$, causes corresponding fluorescence fluctuations, $\delta F_j(t)$, that are measured directly, typically using a confocal fluorescence microscope (Koppel *et al.*, 1976; Qian and Elson, 1991). A fluorescence fluctuation is related to a concentration fluctuation by adding the contributions from different locations in the observation region weighted by the excitation intensity,

$I(r) : \delta F_j(t) = Q_j \int I(r) \delta C_j(r, t) dr$, where Q_j is a constant that accounts for the absorption coefficient and fluorescence quantum yield of the fluorophore (component j) and properties of the optical measurement system. The durations of the fluctuations depend on the size of the volume and the diffusion rate as well as on the chemical reaction rate(s) and for nonlinear chemical reactions, the concentrations of the reactants. It is not sufficient, however, simply to measure one or a few fluctuations to derive the diffusion coefficients and rate constants because the fluctuations are stochastic. Each fluctuation can differ substantially from the others. Therefore, it is necessary to carry out a statistical analysis of the time courses of many fluctuations to obtain accurate values of transport and reaction rate parameters. The statistical analysis of the fluorescence fluctuations is most often carried out by calculating a fluorescence fluctuation autocorrelation function:

$$G_{jj}(\tau) = \frac{\langle \delta F_j(t) \delta F_j(t + \tau) \rangle}{\langle F_j(t) \rangle^2},$$

where $\langle \dots \rangle$ denotes an average over many time points and the division by $\langle F_j(t) \rangle^2$ yields an expression independent of the excitation laser power and fluorophore brightness for a single component system. The fluorescence fluctuation at some time t is multiplied by a fluctuation at a later time $t + \tau$. Averaging many of these products obtained for different times, t , yields an indication of the extent to which the fluorescence/concentration fluctuations have relaxed toward the steady state value for the system during the delay time τ . Then, carrying out this operation for a range of τ values gives a functional form for $G_{jj}(\tau)$ that is characteristic for specific transport processes and chemical reactions (Elson, 2011).

Up to now the fluorescence fluctuations and the fluctuation autocorrelation function has been discussed from a conventional chemical perspective. It may also be of interest to frame the discussion from the point of view of contemporary single molecule studies. This discussion is presented in the Appendix. The final results of the derivations, whether from a chemical or a single molecule perspective, must, of course, yield the same equations for the fluorescence fluctuation autocorrelation function.

The form of $G_{jj}(\tau)$ also depends on the 'shape' of the volume or area from which the fluorescence is detected. This is frequently approximated as a Gaussian function with a characteristic width, w , in the focal $(x - y)$ plane and a width w_z along the optical $(z -)$ axis: $I = I_0 \exp\left[-\frac{2(x^2 + y^2)}{w^2}\right] \exp\left(-\frac{2z^2}{w_z^2}\right)$. As an example, for fluorescent compound j with diffusion coefficient D_j that is diffusing in a two-dimensional plane, for example, a biological membrane:

$$G_{jj}(\tau) = \frac{G_{jj}(0)}{1 + \frac{\tau}{\tau_{Dj}}}; \text{ the characteristic time is } \tau_{Dj} = \frac{w^2}{4D_j}.$$

For chemical reaction kinetics $G_{jj}(\tau)$ can have a number of exponential relaxation components. The amplitude of the correlation function depends only on the concentration and size of the observation area/volume defined by the focused laser. The relative size of the fluctuations is determined by a Poisson distribution that governs the number of molecules in an open volume. Thus, $G_{jj}(0) = \frac{1}{\langle N_j \rangle}$, where for a two-

dimensional system, for example, $\langle N_j \rangle = \pi w^2 \langle C_j \rangle$, the average number of fluorescent molecules of the j 'th chemical species in the observation area πw^2 (Elson, 2013a,b). This property of $G(0)$ provides an absolute measurement of the concentration of the fluorescent component and also the 'brightness' $\langle Q_j \rangle = \frac{\langle F_j \rangle}{\langle N_j \rangle} = G(0) \langle F \rangle$, the average number of fluorescence photons detected per unit time per fluorescent molecule. Many reviews and primary articles provide more details about the forms of correlation functions for different dynamic processes (e.g., Elson and Magde, 1974; Digman and Gratton, 2011; Elson, 2011, 2013a,b; Ries and Schwille, 2012). In systems with M fluorescent components, the contributions of all the fluorophores must be included in the correlation function. The total fluorescence fluctuation is $\delta F(t) = \sum_{j=1}^M \delta F_j(t)$ and the correlation function is

$$G(\tau) = \frac{\sum_{j=1}^M \sum_{k=1}^M \langle \delta F_j(t) \delta F_k(t + \tau) \rangle}{\left(\sum_{j=1}^M \langle F_j(t) \rangle \right)^2}.$$

For the simple example of a multicomponent system in which the only dynamic process is the independent diffusion of noninteracting molecules $\langle \delta F_j(0) \delta F_k(\tau) \rangle = 0$ for $j \neq k$. Then,

$$G(\tau) = \frac{\sum_{j=1}^M \frac{Q_j^2 \langle C_j \rangle}{1 + \frac{\tau}{\tau_{Dj}}}}{\pi w^2 \left(\sum_{j=1}^M Q_j \langle C_j \rangle \right)^2}.$$

If system components interact, as in chemical reactions, the situation is more complicated, especially if the kinetics of the reactions must be taken into account (Elson and Magde, 1974). For example, for the simplest reaction, $A \xrightleftharpoons[k_b]{k_f} B$, in a closed system the chemical relaxation can be described in simple terms $\delta C_B(t) = \delta C_B(0) \exp(-Rt) = -\delta C_A(t)$, where $R = k_f + k_b$. In contrast for an FCS measurement in the open observation region, the kinetics must be analyzed as a two component coupled reaction-diffusion system because the A and B molecules can independently diffuse into and out of the observation region (Elson and Magde, 1974). Although the reaction-diffusion systems are more complicated to analyze, there are standard methods for solving the equations describing them, and so the mathematic analysis does not present a fundamental problem. More important for measuring chemical kinetics by FCS is to find a substantial change in fluorescence that indicates the reaction progress.

Relationship between FCS and Fluorescence Photobleaching Measurements

Both the interpretive theory (Elson, 1985) and the implementation of measurements on a confocal fluorescence microscope (Koppel *et al.*, 1976) are very similar for FCS and fluorescence photobleaching. The main difference in principle between the two kinds of measurements is that FCS relies on spontaneous microscopic concentration (fluorescence) fluctuations in mesoscopic systems, i.e., systems in which there are so few molecules that the concentration fluctuations are readily measured compared to the mean concentrations. In contrast, photobleaching recovery uses a pulse of intense light to photolyze fluorophores irreversibly within a small

observation volume. This produces a localized macroscopic concentration gradient, i.e., a relatively large difference between the concentration in the observation volume and the mean concentration in the surrounding regions of the system. The measured rate of relaxation of the concentration in the observation volume back to its equilibrium value due to diffusion or chemical reaction then provides the desired kinetic parameters. For FCS many stochastic fluorescence fluctuations, no matter how accurately each is measured, must be analyzed statistically via the correlation function to obtain accurate values of phenomenological diffusion coefficients and rate constants. In contrast, in a photobleaching measurement, a single macroscopic relaxation is sufficient to provide the phenomenological coefficients to an accuracy determined by the accuracy of the single measurement. The theoretical basis for supposing that the coefficients determined by each approach are the same is Onsager's regression hypothesis (Onsager, 1931). During its early days FCS was difficult to use to measure processes in cells because the signals were relatively small and could be easily corrupted by cellular motions and other changes of cell properties during the time required to acquire a sufficient number of fluorescence fluctuations. Photobleaching was then more useful for measurements on live cells (e.g., Peters *et al.*, 1974; Edidin *et al.*, 1976; Schlessinger *et al.*, 1976a,b). For the last two decades, however, due to technological advances, especially the use of confocal microscopy to minimize the observation volume (Koppel *et al.*, 1976; Rigler, 1995), FCS has also proved to be useful for studies in living cells.

Initial FRAP measurements were carried out using a non-scanning confocal microscope. Fluorescence emission was measured from a single diffraction-limited spot in the sample defined by the incident laser beam and the confocal aperture. The duration of the bleach pulse, controlled by a fast mechanical or acousto-optical shutter could be very brief ($\sim < 1$ ms) and data could be essentially continually recorded from the single spot (Koppel *et al.*, 1976). More recently confocal laser scanning microscopes have been used for photobleaching measurements (Braga *et al.*, 2004; Seiffert and Oppermann, 2005; Kang *et al.*, 2012). Although this approach has the advantages of availability on a commercially available platform and of the possibility of bleaching and acquiring recovery data from arbitrarily shaped observation regions, very fast processes are less accessible by this approach due to its dependence on the scan speed of the microscope. Moreover, the interpretation of the recovery can be complicated by the need to account for the scanning rate of the microscope (e.g., Braeckmans *et al.*, 2003).

FCS as a Single Molecule Approach

FCS provides a bridge between population and single-molecule approaches. Simple diffusion measurements are instructive. Because FCS measurements are carried out in very dilute solutions, interactions among diffusing fluorophores are minimal, and so the solution is essentially ideal. As a result a molecule moving in this kind of system correlates only with itself. (In this respect FCS is a single molecule measurement.) It is also worth noting that increasing the sensitivity of

measurements to the level of detecting a single fluorophore by minimizing the observation volume (and therefore the interfering background fluorescence) was a major step in facilitating FCS measurements (Mets and Rigler, 1994; Rigler, 2009).

Experimental Considerations

Instrumentation and Observation Volume

The primary task in an FCS measurement is to record the number of photon counts measured during each of a sequence of fixed time intervals or 'bins.' Subtraction of the mean photon count from the counts for each bin yields the time sequence of count fluctuations, the digital representation of the fluctuations of the theoretical continuous fluorescence intensity. The experimental correlation function is calculated from these photon count fluctuations. Fitting the theoretical correlation function, calculated as described above, to the experimental correlation function tests the adequacy of the model and yields values for the model's parameters.

At a minimum an instrument for measuring FCS requires an excitation light source (typically a laser), an optical system to convey the excitation light to the sample and the emitted fluorescence to a detector such as a photomultiplier or avalanche photodiode, and the means to compute the correlation function from record of the fluctuating fluorescence intensity. The optical system is typically a confocal fluorescence microscope (Koppel *et al.*, 1976; Krichevsky and Bonnet, 2002). Very capable and versatile systems for FCS measurements are available commercially from suppliers such as Zeiss, Leica, Olympus, ISS, and others. A critical function of the optical system is to determine the shape of the observation volume or area, i.e., the region of the sample from which emitted fluorescence is detected. This volume is determined by the set of lenses and apertures that shape the excitation beam and by the confocal aperture that determines what emitted photons reach the detector (Koppel *et al.*, 1976; Qian and Elson, 1991). It is common to approximate the observation volume as a three-dimensional Gaussian function defined by beam width, w , in the focal plane and a different beam width, w_z , along the optical(z)-axis, as defined above. This yields a simple correlation function for diffusion of a single fluorophore component (Aragon and Pecora, 1976):

$$G(\tau) = \frac{1}{\langle N \rangle} \frac{1}{\left(1 + \frac{\tau}{\tau_D}\right)} \frac{1}{\left(1 + \frac{\tau}{\tau_{Dz}}\right)^{\frac{1}{2}}}.$$

As before $\tau_D = \frac{w^2}{4D}$ and $\tau_{Dz} = \frac{w_z^2}{4D}$. This approximation can lead to inaccurate measurements for observation volumes defined by diffraction limited laser illumination (Hess and Webb, 2002). One way to minimize this effect is to use two-photon excitation (2PE) to define the observation volume (Berland *et al.*, 1995; Schwille *et al.*, 1999). In addition to providing an observation volume that conforms more closely to a three-dimensional ellipsoidal Gaussian (Hess and Webb, 2002), 2PE also can penetrate deeper into cells while exposing them to less damaging low wavelength excitation light outside the observation volume.

Nanophotonic and Super-Resolution Approaches

The size of the observation region, defined by the values of w and w_z , determine the spatial resolution of an FCS measurement. Because of diffraction in the range of visible light $w > \sim 300 - 250$ nm and $w_z > \sim 500 - 700$ nm. It would be desirable to reduce the values of w and w_z to make possible measurements in small compartments such as endocytic vesicles, to reduce background fluorescence, to enable measurements at higher fluorophore concentration, and to diminish the time needed to measure very slow diffusion. For more than 30 years total internal reflection microscopy (TIRFM) has been used to confine the observation region to within very small distances from a glass substratum for both FCS and photobleaching measurements (Thompson *et al.*, 1981; Lieto *et al.*, 2003; Ohsugi *et al.*, 2006; Vobornik *et al.*, 2008). TIRFM does not, however, confine the observation region parallel to the optical axis. Among several methods developed to provide 'super resolution' (Toomre and Bewersdorf, 2010), stimulated emission depletion (STED) microscopy holds great promise for FCS measurements (Hell and Wichmann, 1994). The particular advantage of STED microscopy is that provides detection volumes with linear dimensions < 50 nm while retaining the ability to make rapid measurements (< 0.1 ms). For example, STED FCS measurements have revealed that cholesterol-rich nanodomains (< 20 nm) transiently trap proteins anchored to a cell membrane by glycerophosphatidylinositol tethers (Eggeling *et al.*, 2009). A general discussion of the application of STED FCS to membrane structure and an extension of the approach to raster scanning have recently appeared (Hedde *et al.*, 2013; Mueller *et al.*, 2013). Further extensions of FCS technology are also possible using nanophotonics (Wenger and Rigneault, 2010).

Errors

Systematic errors in FCS measurements are consistent from one measurement to another and can result from faults in the alignment of the optics, anomalies due to photobleaching and photophysical effects such as blinking, optical saturation, and triplet state decay, mischaracterization of the shape and size of the observation volume, detector artifacts, and other sources (Ries and Schwille, 2012). Random errors due to shot noise can be minimized by increasing the rate of fluorescence photon counts acquired. Eventually, however, there will be a point of diminishing returns when increasing excitation intensity causes unacceptable photobleaching of the fluorophores. Even if shot noise were negligible and each fluorescence fluctuation could be measured with high accuracy, the accurate determination of the phenomenological rate coefficients would nevertheless require measuring many fluctuations due to the stochastic behavior of the mesoscopic molecular system being observed. Evaluation of the random noise for FCS measurements can be based on theoretical calculation of the variance of the correlation function (Koppel, 1974; Qian, 1990; Kask *et al.*, 1997; Saffarian and Elson, 2003). Another approach is to use multiple measurements to estimate variance empirically (Wohland *et al.*, 2001). An apparently good fit of a measured to a theoretical correlation function guarantees neither that the model correctly represents the experimental system nor that

the derived parameters are accurate. It is important to test the model in as many ways as possible (e.g., Saffarian *et al.*, 2004). It is also important to evaluate systematic and random errors of FCS measurements both to optimize experimental accuracy and to have a quantitative sense of the accuracy of the evaluated phenomenological parameters.

Measurement of Molecular Association and Aggregation

FCS and its extensions provide a variety of ways to detect and measure the association of different molecular species with one another and the aggregation of molecules in and on cells. An elementary approach is through the diffusion rate, which depends on the size of the diffusing particle. In a simple solution the diffusion coefficient, D is given by the Einstein relation: $D = \frac{k_B T}{f}$, where k_B , T , and f are Boltzmann's constant, the absolute temperature and the frictional coefficient, respectively. For a spherical particle of radius a in a solution of viscosity η , $f = 6\pi\eta a$, and so the diffusion coefficient varies only as the cube root of the molecular weight. Then, if two spherical molecules of the same volume combine to form a particle, also regarded as spherical, of twice the volume, the diffusion coefficient will decrease by only $\sim 26\%$ ($2^{1/3} - 1$). Unfortunately, mainly because diffusion correlation functions even for single components are spread over a wide time range (due to the dependence on $\frac{G(\tau)}{G(0)} = \frac{1}{1 + \frac{\tau}{\tau_D}}$), it is difficult to resolve diffusion coefficients that are not very different from one another. It has been shown that even with good data (high photon count rates) it is possible to distinguish two components of comparable brightness by FCS only if their diffusion times differ by at least a factor of 1.6 (Meseth *et al.*, 1999). Thus a fourfold volume/weight change would be required to detect an aggregation or association process. Nevertheless, this approach can be useful for detecting the binding of a small fast diffusing molecule to a larger slow diffusing one. Several other approaches provide more sensitive indications of binding or aggregation.

Molecular Association Measured by Two-Color Cross-Correlation Spectroscopy

Fluorescence cross-correlation spectroscopy (FCCS) measures interactions among fluorophores that can be detected at different wavelengths. Suppose that the fluorescence of components A and B can be distinguishably measured at well-separated emission wavelengths λ_A and λ_B . The cross correlation function is

$$G_{AB}(\tau) = \frac{\langle \delta F_A(t) \delta F_B(t + \tau) \rangle}{\langle F_A(t) \rangle \langle F_B(t) \rangle}.$$

If A and B molecules move independently of each other, there is no correlation, and so $G_{AB}(\tau) = 0$. If, however, A and B are bound together, their fluorescence fluctuations are correlated. Then the amplitude $G_{AB}(0)$ indicates the fraction of A and B in complex and can also provide information about the stoichiometry of the complex (Kim *et al.*, 2005). To achieve accurate results, however, there are many practical issues that must be

addressed, including optimizing the overlap of the observation volumes for the two fluorescence wavelengths, saturation of the fluorophores at high excitation intensities, cross talk between the detected emission of the two fluorophores that can produce false cross-correlation, and the effects of photobleaching (Bacia *et al.*, 2006; Bacia and Schwille, 2007).

Aggregation Measured by the Photon Count Histogram

Formation of molecular aggregates, for example, of triskelions in the formation of coated pits (Pearse and Crowther, 1987), and of polymers such as actin microfilaments and tubulin microtubules (Frieden, 1985; Cooper, 1991), and also intermediate filaments that have tissue-specific monomers (Herrmann and Aebi, 2004), are essential processes in establishing cell structure and function. As a simple formal example, consider the aggregation reaction, $nA_1 \rightleftharpoons A_n$. In contrast to the weak dependence of diffusion coefficient on molecular size, the brightness scales linearly with the number of fluorescent particles in an aggregate. The brightness of A_n , containing n fluorescent molecules ('monomers') would be n -fold greater than that of the individual monomers, A_1 , as long as there were no electronic interactions among the monomers in the aggregate that quenched or enhanced their fluorescence. Therefore, A_1 and A_n can much more readily be distinguished by their brightness than by their diffusion coefficients. As we have seen the brightness of an individual component is readily determined as $\langle Q \rangle = \langle F(t) \rangle G(0)$. For typical aggregation or polymerization systems, however, assuming that the system contains only A_1 or A_n is a gross oversimplification. Rather there will typically be not only both A_1 and A_n but also intermediate species A_j , $j = 2 \dots n-1$. Therefore one ought to determine the set $\{\langle N_j \rangle, \langle Q_j \rangle\}$, the average molecule numbers and brightnesses of all species j in the system. This can be done in principle using the photon count histogram (PCH). The PCH is the probability distribution, $P(k)$, of finding k photons in any time bin. As with the correlation function the PCH can be calculated theoretically for different models of $\{\langle N_j \rangle, \langle Q_j \rangle\}$ and then fitted to the experimental PCH to determine the optimal values of $\langle N_j \rangle$ and $\langle Q_j \rangle$. There are several practical approaches to comparing experimental data to the model calculations including via the moments of the distribution (Qian and Elson, 1990) and via direct comparison with the PCH (Chen *et al.*, 1999) or its generating function (Kask *et al.*, 1999). PCH analysis has proved useful in a number of applications including among many others, studies of the formation of oligomeric complexes in cells (Chen *et al.*, 2003), the clustering of EGF receptors in the absence of EGF (Saffarian *et al.*, 2007), the formation of virus-like capsids in infected cells (Chen *et al.*, 2009).

Although the methods derived from the PCH can in principle yield values of $\langle N_j \rangle$ and $\langle Q_j \rangle$ for systems with many components with different brightnesses and concentrations, in practice there are limits on the numbers of components for which these parameters can be accurately evaluated (Pryse *et al.*, 2012). It appears that one of the underlying factors is a kind of ambiguity that results from the Gaussian laser excitation profile almost universally used in these kinds of measurements. A dim particle passing through the center of the

laser beam will contribute a fluorescence pulse that is comparable to a bright particle passing through the dimmer parts of the beam. Computational modeling shows that this apparent ambiguity can be resolved by acquiring a sufficient number of fluctuation measurements but the large number required may be impractical to obtain, especially on labile systems such as cells.

Aggregation by Image Correlation Spectroscopy

Imaging methods can measure fluctuation amplitudes that provide information about aggregation of fluorescent cellular constituents. Similar in principle to a time record of fluorescence fluctuations, spatial fluorescence fluctuations can be measured and auto-correlated from a two-dimensional image of a cell. This approach, called Image Correlation Spectroscopy, supplies a two-dimensional spatial fluorescence fluctuation autocorrelation function $G_{ICS}(x, y)$ (Petersen *et al.*, 1993). Then, (as for the temporal autocorrelation discussed above) for a one component system, $G_{ICS}(0, 0) = \frac{1}{\langle N \rangle}$ where $\langle N \rangle$ is the average number of particles in the observation area. For a one component aggregation system in which the aggregates contain m 'monomers,' the brightness of the aggregate is $Q_m = G_{ICS}(0, 0) \langle F \rangle$ and so the number of monomers in the aggregate is $m = \frac{Q_m}{Q_1}$ where Q_1 is the brightness of the monomer. One should note that while FCS measures fluctuations over time and so requires that the fluorescent particles of interest to move through the observation region, ICS is independent of dynamic properties and can measure aggregation of immobile structures. Both static and dynamic properties of aggregates are observable using more complex image correlation methods that include spatiotemporal ICS measurements carried out on a temporal sequence of images (Kolin and Wiseman, 2007). For example, this approach can show the direction and velocity of convective transport of fluorescent particles (Hebert *et al.*, 2005). A related method been cast in a form that readily takes into account fluctuations due to detector noise and autofluorescence to provide the number and brightness of fluorescent particles taken to comprise a one-component system (Digman *et al.*, 2008a,b). As an example, this approach has been applied to the determination of the clustering of ErbB1 (the EGF receptor) and ErbB2 in the presence and absence of EGF (Nagy *et al.*, 2010).

Summary

1. FCS can be used to measure both dynamic processes such as diffusion, convection, and chemical reaction kinetics and equilibrium properties such as concentrations and extents of aggregation of fluorescent molecules in very small systems. The laser-illuminated observation region can be of diffraction limited size (femtoliters) providing very high spatial resolution that allows comparison of properties of different regions and compartments of cells. The dynamic range is very broad, from microseconds to seconds.
2. FCS is based on measuring processes in mesoscopic systems, i.e., systems that contain small numbers of the fluorescent molecules of interest. Therefore it is necessary to

acquire a large number of fluctuations that must be averaged, usually by calculating a fluorescence fluctuation autocorrelation function. The time needed for the acquisition of these fluctuations determines how rapidly the measurements can be accomplished.

3. FCS is optimal for measurements of systems with fluorophores at very low concentration (nanomolar range) and with characteristic times, for example, τ_D , ranging from microseconds to seconds. Photobleaching recovery is suited to systems with higher concentrations and with times ranging from ~ 100 ms to many seconds. In contrast to the requirement by FCS for many fluctuations to achieve accuracy, a single photobleaching recovery measurement is sufficient to determine rate coefficients to the precision of the measurement of the recovery transient. Therefore, photobleaching is advantageous for measuring on moving cells. Also photobleaching is useful for measuring the time course of exchange reactions (McNally *et al.*, 2000). Nevertheless, FCS can provide information such as absolute fluorophore concentrations and extents of aggregation that are inaccessible to photobleaching recovery.
4. FCS has given rise to a large number of extensions that are useful for specific purposes, for example, two-color FCCS to measure association of fluorescent 'monomers' and image correlation spectroscopy to measure aggregation.
5. FCS has been applied to a wide range of cell biological questions, for example, among many others, detection and measurement of receptor clustering (Saffarian *et al.*, 2007; Nagy *et al.*, 2010), probing the endocytic pathway using two-color cross-correlation spectroscopy (Bacia *et al.*, 2002), measurement of the dynamics of paxillin molecules during cell adhesion (Digman *et al.*, 2008a,b).

Appendix

We have provided the conventional definition of the correlation function in terms of chemical concentrations, but it is instructive also to consider an equivalent definition from the perspective of contemporary single molecule studies. We will be concerned with mesoscopic systems in which there are a small number of fluorescent molecules of interest the positions of which fluctuate continuously over time. We therefore adopt a probabilistic point of view: $p(r, t)$ is the probability that a fluorescent particle is at position r at time t . The fluorescence intensity measured from a single molecule can be represented as $F(t) = Q \int I(r) p(r, t) d^3 r$ where $I(r)$ is the fluorescence intensity detected from position r , and Q is a brightness parameter, i.e., the emitted intensity measured from a single fluorescent molecule, as defined above. Then, for a system that contains a single fluorescent molecule the normalized and non-normalized correlation functions, $G_1(\tau)$ and $g_1(\tau)$, respectively, are

$$\begin{aligned} G_1(\tau) &= \frac{g_1(\tau)}{\langle F(t) \rangle^2} = \frac{\langle F(t) F(t + \tau) \rangle}{\langle F(t) \rangle^2} \\ &= \frac{Q^2 \int I(r_0) I(r) p(r_0, 0) W(r|r_0, \tau) d^3 r_0 d^3 r}{\langle F(t) \rangle^2} \end{aligned}$$

In this equation, and $W(r|r_0, \tau)$ is the probability that the molecule initially at r_0 will be at position r at a later time τ . A freely diffusing molecule is equally likely to be anywhere in the sample volume, and so $p(r_0, 0) = \frac{1}{V}$, where V is the total volume of the system. The transition probability for simple diffusion with diffusion coefficient D is

$$W(r|r_0, \tau) = \frac{1}{(4\pi D\tau)^{3/2}} \exp\left[-\frac{|r - r_0|^2}{4D\tau}\right].$$

For simplicity we now restrict ourselves to two-dimensional systems; the results are readily extended to three dimensions by taking into account the detected intensity along the z -axis of light propagation. FCS measurements commonly use a Gaussian laser intensity profile, that yields a detection function represented in the focal plane as $I(r) = \exp\left(-\frac{2r^2}{w^2}\right)$ with $r = (x, y)$ and w , the radius of the Gaussian detection area. This yields,

$$\begin{aligned} g_1(\tau) &= \frac{Q^2}{V} \int \exp\left(-\frac{2r_0^2}{w^2}\right) \exp\left(-\frac{2r^2}{w^2}\right) W(r|r_0, \tau) d^2 r_0 d^2 r \\ &= \frac{Q^2}{V} \int \exp\left(-\frac{2r_0^2}{w^2}\right) \exp\left(-\frac{2r^2}{w^2}\right) \frac{1}{(4\pi D\tau)} \\ &\quad \exp\left[-\frac{|r - r_0|^2}{4D\tau}\right] d^2 r_0 d^2 r. \end{aligned}$$

Here we have used $W(r|r_0, \tau)$ for a two-dimensional system.

Extension of the correlation function for a one-particle system to a system containing N_t fluorescent particles is complicated by the fact that the probability distribution function for N particles is the N -fold convolution of the distributions for single particles. It is useful to avoid convolutions by noting that $g_1(\tau)$ can be regarded as a moment of a bivariate distribution the two dimensions of which correspond to the fluctuating fluorescence intensity record and the same record delayed by lag time τ (Melnykov and Hall, 2009). Then, one may use the additive properties of cumulants, a related type of moment, so that $g_1(\tau) = \kappa_1(\tau)$ where $\kappa_1(\tau)$ is a cumulant (Qian and Elson, 1990; Wu *et al.*, 2008; Melnykov and Hall, 2009). Since cumulants are additive, for a system containing N molecules, $\kappa_N(\tau) = N\kappa_1(\tau)$. This leads to the following expression for the correlation function:

$$\begin{aligned} g_N(\tau) &= \frac{N_d Q^2}{A_d} \int \exp\left(-\frac{2r_0^2}{w^2}\right) \exp\left(-\frac{2r^2}{w^2}\right) \frac{1}{(4\pi D\tau)} \\ &\quad \exp\left[-\frac{|r - r_0|^2}{4D\tau}\right] d^2 r_0 d^2 r. \end{aligned}$$

Here, $A_d = \pi w^2$ is the area from which the fluorescence is detected, and N_d is the number of molecules in that area. (Thus the concentration of the fluorescent particles is $C = N_d/A_d$.) It can further be shown that carrying out the integrations in this equation yields the expected form of the correlation function for simple diffusion (Elson and Magde, 1974).

Glossary

Autofluorescence Fluorescence from endogenous compound in biological material.

Fluorescence decay function The waveform of the fluorescence signal emitted from an ensemble of fluorescent molecules after excitation with a short light pulse.

Fluorescence lifetime The average time a molecule stays in the excited state after being excited by absorbing a photon.

Förster resonance energy transfer (FRET) Energy transfer from an excited molecule (the donor) into another molecule (the acceptor) located in close proximity to it.

Phasor A pointer describing phase and the modulation degree of a periodic light signal.

Time-correlated single-photon counting A technique to record the waveform of a periodical optical signal by recording single photons, measuring the time differences of these photons to a reference signal synchronous with the optical signal, and building up the distribution of the number of photons over the time difference.

Fluorescence

Techniques based on fluorescence detection have found broad application in cell biology because they are extremely sensitive and able to deliver information about biochemical interactions on the molecular scale. Fluorescence techniques obtained a significant boost by the development of labeling and transfection techniques which permit the fluorophores to be placed into defined biological targets. Cells could now be genetically manipulated to express fluorophores in exactly defined target positions within the cell's intrinsic proteins (Chalfie *et al.*, 1994; Tsien, 1998). Another improvement was the introduction of confocal and multiphoton laser scanning microscopes (Denk *et al.*, 1990; Pawley, 2006; Wilson and Sheppard, 1984). By confining the detection to a well-defined focal plane, these instruments significantly improved the specificity of the data recorded.

Fluorescence is a process in which a molecule enters an excited electronic state by absorbing an optical photon and returns from this state by emitting a photon of longer wavelength. The mechanisms involved in fluorescence are summarized in Figure 1. For a comprehensive description of fluorescence, please see Lakowicz (2006).

The ground state is S0, the first excited state S1. By absorbing a photon with an energy higher than the gap between S1 and S0, the molecule transits into the S1 state. Higher excited states, S2, S3, do exist and can be excited, but decay at an

extremely rapid rate into the S1 state. Moreover, the electronic states of the molecules are broadened by vibration. Therefore, a molecule can be excited by a photon of almost any energy higher than the gap between S0 and S1.

A molecule can also be excited by absorbing two photons simultaneously (Göppert-Mayer, 1931). The sum of the energy of the photons must be larger than the energy gap between S1 and S0. Multiphoton absorption has long been only a theoretical possibility. However, it is easily achieved in the focus of a picosecond or femtosecond pulsed laser. Multiphoton excitation has therefore become a standard technique of laser scanning microscopy (Denk *et al.*, 1990; Diaspro, 2001; Pawley, 2006).

Without interaction with its environment, the molecule can return from the S1 state by emitting a photon or by internally converting the absorbed energy into heat. Moreover, the molecule can interact with its environment and return to the ground state by transferring the energy to another molecule, see Figure 1, left. Effects that let molecules lose their excitation energy to their environment are usually summarized by the term 'fluorescence quenching.'

Figure 1 shows that molecules that absorb light are, in principle, also able to emit fluorescence. How much fluorescence is emitted for a given amount of absorbed light depends on the balance of the radiative and non-radiative decay rates. Molecules in which the emission of fluorescence is the dominating decay path are called fluorophores.

Figure 1 Left: General mechanisms involved in Fluorescence. Middle: fluorescence spectrum. Right: Fluorescence decay.

An excited molecule can also transit into a triplet state, T1. The 'intersystem crossing' rate is normally much smaller than the S1–S0 transition rate. Except for a few special cases intersystem crossing has therefore little influence on the fluorescence. However, the triplet state is a starting point for photochemical reactions. Excessive population of triplet states may therefore have an impact on the viability of cells and on the photostability of fluorophores.

If an ensemble of identical molecules is excited, individual molecules end up in different vibrational levels of the ground state. Thus, the fluorescence spectrum has a nonzero width, see [Figure 1](#), middle. The center wavelength and the shape of the spectrum are characteristic of the type of the molecule. Because emission, internal conversion, and quenching are competing, the fluorescence intensity changes with the rate constants.

If the same ensemble of molecules is excited with short light pulses the fluorescence intensity will rise with the excitation pulse and then decay at a rate equal to the sum of the radiative and non-radiative decay rates, see [Figure 1](#), right. The average time the molecules stay in the excited state is called the 'fluorescence lifetime.' Consequently, fluorescence signals are characterized by three parameters:

The 'intensity' of the fluorescence depends on the ratio of the radiative and non-radiative decay rates and thus on the molecular environment of the fluorophore. However, it also depends on the concentration of the fluorophore. Changes in the decay rates therefore cannot easily be distinguished from changes in the concentration. Images of the fluorescence intensity do, however, show where in a sample a fluorophore is located, and show the spatial structure of the specimen.

The 'fluorescence spectrum' is determined by the S1–S0 energy difference, and the width of the vibration bands. It is thus characteristic of the fluorophore. The shape of the fluorescence spectrum is, within reasonable limits, independent of the fluorophore concentration. Images containing spectral information thus allow the fluorophores in the individual pixels of an image to be identified.

The 'fluorescence lifetime' or, more exactly, the 'fluorescence decay function,' depends on the type of the fluorophore but not on its concentration. It depends also on the molecular environment of the fluorophore. It is influenced by the presence of fluorescence quenchers and their local concentration, by binding of the fluorophore to different biological targets, by the folding state of the binding targets, or by the presence of other optical absorbers which it may interact with by Förster energy transfer ([Förster, 1948, 2012](#)). Fluorescence decay functions and, consequently, fluorescence lifetime images, can therefore be used to obtain information on the molecular environment of the fluorophore molecules ([Becker, 2012](#); [Berezin and Achilefu, 2010](#); [Lakowicz, 2006](#)).

There are a number of different techniques to record fluorescence decay functions, and to combine fluorescence decay recording with imaging. The techniques can be classified into time-domain and frequency-domain techniques, photon counting and analog techniques, and point-scanning and wide-field imaging techniques. It also matters whether a technique acquires the signal waveform in a few time gates ([Buurman *et al.*, 1992](#)) or in a large number of time channels ([Becker *et al.*, 2004](#)), and whether this happens simultaneously ([Becker *et al.*, 2004](#); [Becker, 2005](#); [Buurman *et al.*, 1992](#)) or

sequentially ([Dowling *et al.*, 1997](#); [Straub and Hell, 1998](#)). Virtually all combinations are in use. This leads to a wide variety of instrumental principles. Different principles differ in their photon efficiency, i.e., in the number of photons required for a given lifetime accuracy ([Gerritsen *et al.*, 2002](#); [Köllner and Wolfrum, 1992](#); [Philip and Carlsson, 2003](#)), the acquisition time required to record these photons, the photon flux they can be used at, their time resolution, their ability to resolve the parameters of multi-exponential decay functions, multi-wavelength detection capability, optical sectioning capability, and compatibility with different imaging and microscopy techniques ([Becker and Bergmann, 2008](#)). The most frequently used fluorescence lifetime imaging (FLIM) techniques are described in section 'Technical Aspects of FLIM.' For the examples given in the section below Time-domain FLIM by time-correlated single-photon counting and laser scanning was used. The technique is not only the most sensitive one but also demonstrates most clearly the dependence of the fluorescence decay behavior on the molecular environment of the fluorophores.

FLIM Applications in Life Sciences

Measurement of Local Molecular Environment Parameters

There is a wide range of mechanisms for environment-induced fluorescence-lifetime changes ([Lakowicz, 2006](#)). The most relevant ones for biological imaging are fluorescence quenching by ions, influence of binding to DNA and RNA ([Van Zandvoort *et al.*, 2002](#)), binding to proteins, influence of the folding of the proteins the fluorophore is attached to, and Förster resonance energy transfer (FRET).

Another mechanism of lifetime changes is that a fluorophore has two forms with different fluorescence lifetimes. This is the case for large group of sensors for Ca^{2+} , Mg^{2+} , Na^{+} , and K^{+} ions. These fluorophores have a cation-bound and a cation-unbound form. The two forms have different fluorescence quantum yields, and thus different lifetimes. The apparent lifetime therefore depends on the concentration of the cation. pH sensors have a protonated and a deprotonated form. The forms have different fluorescence lifetimes. The apparent lifetime thus changes with the concentration ratio of the forms, and thus depends on the pH ([Hanson *et al.*, 2002](#); [Sanders *et al.*, 1995](#)).

There are also effects of local viscosity ([Kuimova *et al.*, 2008](#)), local refractive index ([Strickler and Berg, 1962](#); [Tregido *et al.*, 2008](#)), proximity to nanoparticles and metal surfaces ([Geddes *et al.*, 2003](#); [Muddana *et al.*, 2009](#); [Ritman-Meer *et al.*, 2007](#)), and aggregation of the fluorophore ([Kelbauskas and Dietel, 2002](#)).

[Figure 2](#), left, shows a sample of human skin stained with the pH sensor BCECF (2',7'-bis-(2-carboxyethyl)-5-(and-6)-carboxyfluorescein). The color of the image shows the fluorescence lifetime (mean lifetime of double-exponential decay, see 'FLIM Data Analysis'). Fluorescence decay curves in two selected pixels are shown on the left of the image.

[Figure 2](#), right, shows a barley root stained with the Ca^{2+} sensor Calcium Orange. A lifetime change due to different Ca^{2+} concentration is clearly visible. Fluorescence decay

Figure 2 Left: Lifetime image of skin tissue stained with BCECF. The lifetime is an indicator of the pH. (Theodora Mauro, University of San Francisco, Zeiss LSM 510 NLO with bh SPC-830 TCSPC FLIM module.) Right: Barley root tip, stained with Calcium Orange. Courtesy of Feifei Wang, Zhonghua Chen and Anya Salih, Confocal Bioimaging Facility, University of Western Sydney, Australia. Leica SP5 MP with bh SPC-150 FLIM module.

curves in two selected spots of the image are shown on the right.

Other applications are Cl^- measurements in olfactory sensory neurons (Kaneko *et al.*, 2004), detection of changes in the Cl^- concentration during chloride homeostasis (Gilbert *et al.*, 2007), and on inflammation (Funk *et al.*, 2008). The application of FLIM to determine absolute Ca^{2+} resting concentrations in neurons has been described by Kuchibhotla *et al.* (2009). The detection of transient changes of the Ca^{2+} concentration in neurons on electrical stimulation has been described in Becker *et al.* (2014).

FRET Experiments

The most frequent application of FLIM is the measurement of protein interaction and protein folding by FRET (Förster, 1948, 2012). FRET occurs when the fluorescence emission band of one molecule (the donor) overlaps the absorption band of a second one (the acceptor), and the distance between donor and acceptor is smaller than a few nanometers. The energy absorbed by the donor is then transferred into the acceptor, and emitted via the acceptor fluorescence band. The efficiency of the energy transfer is an indicator of the distance between the donor and the acceptor.

Measurements of FRET by steady-state techniques are difficult: the concentration of the donor and the acceptor changes throughout the sample. The techniques therefore depend on ratios of the donor and acceptor intensities. However, the FRET-excited acceptor intensity is not directly available. There is 'donor bleedthrough' due to the overlap of the donor fluorescence into the acceptor emission band. Moreover, an unknown amount of the acceptor fluorescence comes from direct excitation. Steady-state FRET techniques therefore require careful calibration, including measurements of samples containing only the donor and only the acceptor. Another problem is that not all donor molecules interact with an acceptor, and there is usually a mixture of interacting and noninteracting donor. It therefore cannot be determined whether a variation in the classic 'FRET efficiency' is due to a variation in the distance between donor and acceptor or in the fraction of interacting proteins.

With FLIM, the energy transfer is directly observable as a decrease in the fluorescence lifetime of the donor. Donor

bleedthrough and directly excited acceptor fluorescence have no influence on FLIM-FRET measurements. The only reference value needed is the donor lifetime in absence of the acceptor (Bacskaï *et al.*, 2003; Biskup *et al.*, 2004; Chen and Periasamy, 2004; Duncan *et al.*, 2004; Gukassyan *et al.*, 2007; Periasamy, 2001; Periasamy and Clegg, 2009). It has been shown that even the reference lifetime is not necessarily needed: a part of the donor population does not interact with an acceptor. The lifetime of the noninteracting donor fraction can be extracted from the FLIM data and used as a reference lifetime (Becker *et al.*, 2004; Becker, 2005). The obvious advantage of this approach is that the reference lifetime is obtained from the same pixels of the same cell, and thus from the same molecular environment as the FRET data. Double-exponential FRET analysis is thus, within reasonable limits, independent of lifetime variations induced by variations in the local environment (Becker, 2015a).

An example of a FLIM FRET result is shown in Figure 3. The data were obtained from a cell expressing a green fluorescent protein (GFP) fusion protein and a Cy3-labeled antibody (Bastiaens and Squire, 1999). FRET occurs between the GFP (the donor) and the CY3 (the acceptor). A lifetime image was recorded at the emission wavelength of the GFP. The data were analyzed by a double-exponential decay model. An image of the amplitude-weighted lifetime is shown in Figure 3, left, decay curves in two characteristic pixels in Figure 3, right. The donor lifetime is significantly reduced at the cell membrane, indicating that this is the place where the protein interacts with the antibody.

It should be mentioned here that a number of pitfalls that can impair the results of FRET experiments. If the labeling density or the expression level is too low the fluorescence signals may be contaminated by autofluorescence. If the expression is too high energy can migrate between the donors, and donor molecules may interact with several acceptor molecules. The FRET results then no longer represent the distance between donor and acceptor and the relative amount of interacting donor (Koushik and Vogel, 2008; Vogel *et al.*, 2006). The results can be also biased by photobleaching or photoconversion: the noninteracting donor fraction photobleaches faster, resulting in an apparent increase of the FRET efficiency. Moreover, a part of the donor may be photoconverted and change its fluorescence lifetime (Hoffmann *et al.*,

Figure 3 Cell expressing a GFP fusion protein (donor) and Cy3-labeled antibody (acceptor). Donor image, analysis by double-exponential decay model. Zeiss LSM 710 microscope with Becker and Hickl Simple-Tau 152 FLIM system.

2008). Massive changes in the fluorescence quantum efficiencies and the decay profiles of fluorescent proteins are introduced by fixation techniques (Becker, 2015a). FRET measurements should therefore always be performed on live cells. It should be noted that these problems are not specific of FLIM FRET experiments; they exist also for intensity-based techniques. In any case, FLIM measurements have the advantage that the nature of the problem can be more easily be identified.

An enormous number of FLIM-FRET papers have been published in the last ten years, most of them using time-correlated single-photon counting (TCSPC) FLIM. Please see Becker (2015a) for a review of the FLIM-FRET literature and for further details.

Autofluorescence FLIM

The use of autofluorescence for imaging of biological objects has the obvious benefit that the techniques can directly be transferred into clinical applications, see section below. The problem of steady-state autofluorescence measurement is that biological tissue contains a wide range of fluorophores (König and Riemann, 2003; Richards-Kortum *et al.*, 2003; Schweitzer *et al.*, 2004). The fluorescence spectra overlap, and their apparent shape can be changed by unknown absorbers in the tissue. The evaluation of the tissue state based on intensity imaging and spectral imaging is therefore difficult.

FLIM is often considered only a way to improve the contrast of separation of the different fluorophores. The most important argument for using lifetime imaging is, however, that the lifetimes of many endogenous fluorophores depend on local environment parameters, such as pH, oxygen saturation, on binding to proteins, and, most importantly, on metabolic activity. Autofluorescence lifetime detection therefore not only adds an additional separation parameter but also yields direct information about the metabolic state of the cells

and the microenvironment of the endogenous fluorophores (Bird *et al.*, 2005; Chorvat and Chorvatova, 2006, 2009; Chorvatova *et al.*, 2012; Gukassyan and Kao, 2009; Lakowicz *et al.*, 1992; Paul and Schneckenburger, 1996; Skala *et al.*, 2007a,b, 2010a,b; Szaszak *et al.*, 2011; Wang *et al.*, 2008).

An example is shown in Figure 4. It shows cultured human stem cells excited by two-photon excitation at 750 nm. The detection wavelength was 450–480 nm. Under these conditions, the fluorescence comes predominately from nicotinamide adenine dinucleotide (NADH). The protein-bound form of NADH has a fluorescence lifetime of about 2.5 ns, the unbound form a lifetime of about 500 ps (Lakowicz *et al.*, 1992). The two decay components can be separated by double-exponential decay analysis, see ‘FLIM Data Analysis’. The ratio of the amplitudes of the decay components, a_1 and a_2 , represent the ratio of unbound and bound NADH. It can clearly be seen in Figure 4 that the more differentiated cells have smaller a_1/a_2 (unbound/bound) ratios and longer mean lifetime, t_m . Please see König *et al.* (2011) and Guo *et al.* (2008) for further details.

Autofluorescence FLIM images can be surprisingly rich in detail. An example is shown in Figure 5. The images show a pig skin sample excited by two-photon excitation at 800 nm. The left image shows the wavelength channel below 480 nm. This channel contains both fluorescence and second harmonic generation (SHG) signals (Masters and So, 2008). The SHG signal comes from the collagen fibrils of the skin. The amount of collagen (and thus the relative intensity of SHG signals) can be used to quantify skin ageing (Koehler *et al.*, 2006). The SHG fraction of the signal has therefore been extracted from the FLIM data and displayed by color. The right image is from the channel >480 nm. It contains only fluorescence, the color corresponds to the amplitude-weighted mean lifetime of a double-exponential decay model. The fluorescence comes from a variety of compounds, mainly NADH, flavin adenine dinucleotide (FAD), melanin, and porphyrins, in the cells of the dermis.

Right: Wavelength channel > 480 nm, color shows amplitude-weighted mean lifetime. Microscope Zeiss LSM 710 NLO, with bh Simple-Tau 152 FLIM system.

Clinical FLIM Applications

Multiphoton Tomography of Skin

Multiphoton tomography of human skin uses scanning by a focused femtosecond laser beam, two-photon excitation, and non-descanned detection of the fluorescence signals. The three-dimensional tissue structure can be reconstructed from the data at subcellular resolution. The technique goes back to the work of Gratton, König, Masters, So, and Tromberg who showed that *in-vivo* two-photon autofluorescence imaging of cells and, especially, human skin is possible without impairing viability (König, 2008a; Masters *et al.*, 1997; Masters and So, 1999, 2008). Because the technique is based on fast scanning and pulsed excitation it can easily be combined with TCSPC FLIM. Instruments for clinical application have been developed by Jenlab GmbH, Jena, Germany. Figure 6 shows the stratum granulosum of a human patient recorded with a Jenlab Dermainspect system and a Becker and Hickl SPC-152 FLIM system. For interpretation of skin FLIM images please see Sanchez *et al.* (2015).

An impressive number of papers have appeared related to FLIM data obtained with these instruments, please see

Dimitrow *et al.* (2009), Geusens *et al.* (2010) Kantelhardt *et al.* (2007), König and Riemann (2003), König and Uchugonova (2009), Leppert *et al.* (2006), Lin *et al.* (2011), Patalay *et al.* (2011), Prow *et al.* (2011), Roberts *et al.* (2008, 2011), Sanchez *et al.* (2010), and Szaszak *et al.* (2011). An overview on clinical multiphoton tomography of skin is available in König (2008b) and in Sanchez *et al.* (2015).

Ophthalmic FLIM

FLIM of the human ocular fundus is obtained by combining an ophthalmic scanner with one or several ps diode lasers, and a TCSPC FLIM system. The problems of ophthalmic FLIM are that the excitation power is limited by eye safety considerations, and that motion of the eye during image acquisition must be taken into account. For technical details please see Becker (2015a) and Schweitzer *et al.* (2004, 2007). Ophthalmic FLIM is currently undergoing clinical trials.

Changes in the decay functions can result both from changes in the tissue constitution, and from changes in the local environment of the fluorophores. Distinct signatures in

Figure 6 FLIM image of human skin recorded by a Jenlab Dermainspect Multiphoton Tomograph and a Becker and Hickl SPC-150 TCSPC FLIM system. Two-photon excitation at 750 nm. Data courtesy of Michael Roberts and Washington Sanchez, Brisbane, Australia.

Figure 7 Left: lifetime image of the fundus of a healthy eye. Right: lifetime image of the fundus of an eye suffering from AMD. Amplitude-weighted lifetime of double-exponential decay. Data courtesy of Dietrich Schweitzer, Friedrich Schiller University Jena, Germany, and Heidelberg Engineering, Heidelberg, Germany.

the decay parameters were found for early and late age-related macula degeneration (AMD), for under-supplied regions after arterial branch occlusions, for metabolic alterations due to diabetes mellitus, and for extra-macular drusen (Schweitzer *et al.*, 2009, 2012; Schweitzer, 2009, 2010).

Typical results are shown in Figure 7. The images were scanned by a FLIO (fluorescence lifetime ophthalmoscope) laser ophthalmoscope of Heidelberg Engineering, Heidelberg, Germany. The system uses Becker and Hickl SPC-150 TCSPC FLIM modules to record the FLIM data.

Figure 7, left, shows the ocular fundus of a healthy eye. The image does not show significant pathological alterations. For comparison, a FLIM image of the ocular fundus of a patient with wet AMD is shown in Figure 7, right.

Requirements to a FLIM Technique for Cell Biology

Photon efficiency

FLIM usually requires more photons than intensity imaging. The reason is not that FLIM is 'inefficient,' as it is sometimes

believed. The difference simply results from the fact that FLIM is aiming at recording small changes in the fluorescence behavior of a sample, whereas intensity imaging is used to record the spatial structure of a sample. Lifetime changes in FLIM experiments can be orders of magnitude smaller than (spatial) intensity changes in intensity images. The required signal-to-noise ratio is therefore much higher for FLIM. Both for lifetime recording and intensity recording, the signal-to-noise ratio is the square root of the number of photons per pixel (Gerritsen *et al.*, 2002; Köllner and Wolfrum, 1992). Consequently, typical FLIM experiments need more photons than spatial imaging. Remarkably, the 'efficiency' difference of FLIM and intensity imaging disappears when intensity data are used to derive molecular parameters, as has been demonstrated for FRET experiments (Pelet *et al.*, 2006).

The importance of photon efficiency becomes even more obvious if the samples are considered. Intensity imaging is usually performed on samples stained with high amounts of fluorophores. In contrast, most FLIM are performed on fluorophores attached to highly specific targets in the cells. That means the effective fluorophore concentration is low. The fluorophores have therefore to perform more

excitation-emission cycles, and thus photobleach faster. Moreover, FLIM measurements are usually performed on live specimens. High excitation power easily causes metabolic changes or even damage to the cells. To keep the exposure as low as possible it is essential that the FLIM technique obtains the best possible lifetime accuracy from a given number of photons detected. Photon efficiency (Geritsen *et al.*, 2002; Philip and Carlsson, 2003), i.e., the number of photons required to obtain a given lifetime accuracy, is therefore the most critical parameter of a lifetime imaging technique for biological application.

Single-photon capability

Biological samples, especially live specimens investigated under a microscope, deliver fluorescence intensities no higher than a few million photons per second. Under these conditions, the detector signal is a train of random pulses representing the detection of the single photons (Becker, 2005). The FLIM technique has to efficiently reconstruct the decay functions in the pixels of the image from the single-photon pulses of the detector.

Tolerance to dynamic effects in the sample

Fluorescence signals from live specimens cannot be expected to remain perfectly stable over the acquisition time of the image. A part of the fluorophore may be photobleaching, there may be motion in the samples, and the cells may respond to light-induced stress by changes in their metabolism.

Such changes should not induce direct artifacts, such as distortions in the decay curves, fluorescence spectra, or images recorded. Procedures like slow scanning of time gates or spectral scanning are therefore problematic. If spatial scanning is used, it will be shown that, it has to be faster than the changes in the sample.

Resolution of complex decay profiles

An ensemble of similar molecules in a homogeneous molecular environment delivers a single-exponential fluorescence decay function characterized by a single fluorescence lifetime. In cells and biological tissue the situation is different. The molecular environment of the fluorophore is rarely homogeneous, there may be several fluorophores of different fluorescence lifetime, or different fractions of the same fluorophore may be bound to different molecular targets. Examples are FRET experiments where donor molecules interacting with an acceptor have shorter fluorescence lifetimes than non-interacting ones. The decay profiles then become multi-exponential. Under these conditions, the lifetimes and amplitudes of the individual decay components provide better access to molecular parameters than an average 'lifetime' of the decay function. A FLIM technique for biological application should therefore be able to resolve complex decay profiles into their components.

It should be noted that the number of photons required for a multi-exponential decay analysis is higher than for single-exponential analysis. Köllner and Wolfrum (1992) estimated the number of photons required to resolve a double-exponential decay to be $N=400\,000$. A number of photons per pixel this high is, of course, entirely beyond the limits set by the photostability of a biological sample. Fortunately, the prospects of separating two lifetime components improve dramatically with the ratio of the two lifetimes and with the

amplitude factor of the short lifetime component. The lifetime components assumed by Köllner and Wolfrum (1992) were 10% of 2 ns and 90% of 4 ns. This is an extremely unfavorable situation which indeed requires an extremely high number of photons. Fortunately, the decay profiles encountered in FRET and autofluorescence measurements have a much more favorable composition. Usually the lifetime components are separated by a factor of 5–10, and the amplitude of the fast component is 50–90%. Under such conditions double or even triple exponential analysis is feasible with no more than a few 1000 photons per pixel, and very satisfactory results are obtained from 10 000 photon per pixel.

Time resolution

It is sometimes believed that FLIM does not require a particularly high-time resolution. It is certainly correct that the fluorescence lifetimes of typical fluorophores used as fluorescent labels for cell imaging are on the order of a few ns. However, this does not mean that there are no shorter lifetimes or shorter lifetime components. The lifetime of fast decay components of tissue autofluorescence can be 100 ps or shorter (Schweitzer *et al.*, 2007). The lifetime of the quenched donor fraction in FRET experiments can be as short as 300 ps. Lifetimes of dye aggregates in cells have been found as short as 50 ps (Kelbauskas and Dietel, 2002). The lifetime of fluorophores bound to metallic nanoparticles (Ceddes *et al.*, 2003) can be 100 ps and shorter. To resolve such lifetimes at reasonable efficiency from a multi-exponential decay an instrument response width of 100–200 ps full width at half maximum (FWHM) or shorter is desirable.

Suppression of out-of-focus signals

The optical system used in combination with the FLIM system should suppress the excitation and/or the detection of fluorescence outside the focal plane. It should also avoid the detection of laterally or longitudinally scattered light. Such unwanted signal components would not only blur the images and reduce the image contrast but also mix the decay profiles from different pixels and sample planes. Resolving several decay components present in the same pixel is difficult enough. Contamination of the decay data with out-of-focus signals would change the situation virtually hopeless. The only optical technique that efficiently rejects out-of-focus signals without compromising in-focus efficiency is laser scanning. Depth resolution is either obtained by confocal detection or by multiphoton excitation.

Fast scanning

As mentioned above, scanning must be fast enough to avoid artifacts caused by dynamic effects in the sample. There is also a practical requirement for fast scanning: live samples degrade quickly. There must be a possibility of fast live display for focusing, sample positioning, and adjusting the scan area to the region of interest. This requires a frame rate of at least one frame per second.

Live cell compatibility

Fixation techniques commonly used in microscopy coagulate the proteins or otherwise influence the molecular structure of the sample. In other words, fixation destroys exactly what is to

be investigated by FLIM. The vast majority of FLIM measurements are therefore performed in live cells or tissues. Live cell compatibility means minimizing sample exposure, and minimizing motion artifacts within the acquisition time.

Multiwavelength capability

For a number of applications FLIM has to be recorded in several wavelength intervals. Photobleaching and dynamic effects in the sample normally preclude to record data in several wavelength intervals sequentially. The FLIM technique should therefore be able to record data in several detection channels simultaneously.

FLIM Techniques

Time-domain FLIM by multidimensional TCSPC and laser scanning

Fluorescence decay measurement by TCSPC is based on the excitation of a sample with short laser pulses, the detection of single photons of the fluorescence light, the measurement of the detection times of the photons after the laser pulses, and the buildup of a photon distribution over the detection time (O'Connor and Phillips, 1984). TCSPC requires that the detector detects less than about 0.1 photons per excitation pulse. This was a limitation in early TCSPC implementations with low-repetition-rate light sources. With the excitation pulse rates of 50–80 MHz delivered by modern lasers this is no longer a problem (Becker, 2005).

A more serious limitation of classic TCSPC is that it is intrinsically one-dimensional: it delivers only a waveform of the optical signal. To apply classic TCSPC to FLIM a sample would be scanned with the laser beam, the beam position held steady in each pixel until a full fluorescence decay curve has been acquired, and the process repeated for all pixels of the image. Such implementations have indeed been used (Bugiel *et al.*, 1989) but are not compatible with the fast scan rates used in modern laser scanning microscopes.

Modern TCSPC FLIM uses a multidimensional TCSPC (Becker, 2005, 2015a). The principle is shown in Figure 8. The

technique builds up a photon distribution over several parameters: the arrival times of the photons after the laser pulses, t , and the position of the laser beam, x and y , in the sample. From these parameters, a photon distribution over the spatial coordinates, x , y , and the arrival times of the photons, t , is built up. The result is a three-dimensional data array that represents the pixels of the two-dimensional scan, with each pixel containing photons in a large number of time channels for consecutive times after the excitation pulses.

As classic TCSPC, the principle features near-ideal photon efficiency (Köllner and Wolfrum, 1992; Philip and Carlsson, 2003), extremely high-time resolution, and a sufficiently large number of time channels to resolve multi-exponential decay profiles. It has also a number of additional advantages. An obvious one is that it works at any scan rate. At high scan rates, the recording process becomes more or less random. When a photon is detected it is just stored in a pixel and a time channel of the data array according to its time in the fluorescence decay and the position of the laser beam in the scan area. The buildup of the images can directly be observed and the recording be continued over a collection time – or as many frames of the scan – as to obtain the desired signal-to-noise ratio. Fast scanning also avoids excessive triplet accumulation and heat concentration in the excited spot.

The biggest advantage is, however, that FLIM by multidimensional TCSPC can be extended to record more complex photon distributions. This is achieved by adding additional parameters of the photons to the recording process. These can be the wavelength of the emitted photons, several excitation wavelengths multiplexed at high rate, the time after an external stimulation of the sample, or the time within the period of an additional modulation of the laser. As a result, the technique delivers multiwavelength FLIM data (Becker, 2005; Becker *et al.*, 2007; Rück *et al.*, 2007), FLIM data for several excitation wavelengths (Becker, 2005, 2015a), FLIM data resolving dynamic changes in the sample in the millisecond range (Becker *et al.*, 2014; Becker, 2015b), and simultaneous fluorescence and phosphorescence lifetime imaging (FLIM and PLIM) data (Becker *et al.*, 2011b; Becker, 2015a).

Figure 8 Principle of TCSPC FLIM.

Figure 9 Gated photon counting. Two (or more) gated counters record photons in different time windows.

Figure 10 Gated image intensifier.

Moreover, TCSPC FLIM is perfectly compatible with confocal and multiphoton (Denk *et al.*, 1990; Diaspro, 2001; Pawley, 2006; Wilson and Sheppard, 1984) laser scanning microscopes. TCSPC FLIM thus takes advantage of the optical sectioning capability of confocal or multiphoton scanning: the data are obtained from an accurately defined plane of the sample, without contamination from out-of focus fluorescence or lateral scattering (Becker, 2015b).

In addition to building up FLIM data TCSPC makes the full information about the individual photons available. Such ‘parameter-tagged photon data’ can be used in various ways, for example, for single-molecule detection (SMD) (Prummer *et al.*, 2004; Widengren *et al.*, 2006), fluorescence correlation spectroscopy (FCS), (Becker *et al.*, 2006; Felekyan *et al.*, 2005), and PLIM (Becker *et al.*, 2011b). Please see Becker (2015a) for technical details.

As a disadvantage of TCSPC FLIM it is often stated that TCSPC FLIM is slow in terms of acquisition time. This is not quite correct, as has been shown by Becker *et al.* (2009) and Katsoulidou *et al.* (2007). Certainly, a TCSPC FLIM system cannot record an image faster than the scanner is able to scan the sample. Also, the count rate a TCSPC system can process is limited (Becker, 2005). However, the count rates achieved in typical TCSPC FLIM applications are rather limited by the photostability of the samples than by the counting capability of the FLIM system. Due to its near-ideal photon efficiency, TCSPC FLIM in these cases achieves the shortest acquisition time of all FLIM techniques based on sample scanning.

Gated photon counting

Fluorescence lifetime images can be obtained by scanning the sample with a pulsed laser beam, detecting single photons of

the fluorescence light, and recording the photons in several time-gated counters, see Figure 9, left (Buurman *et al.*, 1992). The fluorescence lifetime is calculated from the counting results in the different time windows, see Figure 9, right. A single-exponential lifetime can be calculated from the intensities, I_a and I_b , in two time windows. Up to four time windows are used to determine lifetime components of multi-exponential decay profiles.

FLIM by gated photon counting works up to very high count rates. Moreover, as long as the fluorescence lifetimes are in a reasonable relation to the width of the time windows, gated photon counting works at high photon efficiency (Gerritsen *et al.*, 2002). The problem of gated photon counting is that the decay profiles are under-sampled. The result therefore depends on the location of the excitation pulse in or before the first time window, and on the transit time spread in the detector. Both parameters cannot be determined directly. Gated photon counting therefore has to rely on calibration with fluorophores of known lifetimes.

Time-domain wide-field FLIM by gated image intensifiers

Image intensifiers are vacuum tubes containing a photocathode, a multiplication system for the photoelectrons, and a two-dimensional image detection system. Multichannel plates are used for electron multiplication, see Figure 10. One microchannel plate gives a typical multiplication factor of 10^3 , a gain of 10^6 can be achieved by two plates in series. With a gain this high, the device is able to detect single photons of the fluorescence signal.

Time resolution is obtained by gating the image intensifier. This is achieved by applying a gating pulse between the multichannel plate and the photocathode or a conductive grid

Figure 11 Principle of frequency-domain FLIM. The fluorescence lifetime is derived from the decrease in the modulation degree and the phase shift of the fluorescence compared to the excitation.

capacitively coupled to it. The fluorescence decay functions are measured by scanning the gate pulse in time, i.e., by taking consecutive images for different delay of the gate pulse, see [Figure 10](#), right.

Image intensifiers are normally used in combination with wide-field excitation ([Dowling et al., 1997](#)) or multiphoton multi-beam scanning ([Straub and Hell, 1998](#)). The advantage of wide-field imaging is that image information is acquired simultaneously for all pixels. Therefore the acquisition times can be made shorter than for techniques based on spatial scanning.

The disadvantage is that gating records only a fraction of the photons. The photon efficiency of the recording is therefore low, and the total sample exposure is high. The efficiency problem can be partially solved by recording only a few time gates. However, this results in under-sampled fluorescence decay data and problems to resolve multi-exponential decay profiles.

Moreover, wide-field excitation does not reject out-of-focus light. Unless the samples are very thin the decay data are thus contaminated by fluorescence from out-of-focus planes. In principle, out-of-focus signals can be removed from the data by structured illumination techniques ([Cole et al., 2001](#)). However, these techniques are based on calculating differences between images recorded for different illumination patterns. Although the result is an image containing only the signal from the focal plane this image contains the shot noise of the photons of all planes from which fluorescence is detected.

Frequency-domain FLIM by laser scanning

Frequency-domain FLIM records differences in the phase and the modulation degree between a modulated or pulsed excitation and the fluorescence signal, see [Figure 11](#). These values translate directly into the fluorescence lifetime.

A commonly used principle of frequency-domain FLIM with laser scanning and single-point detectors is shown in [Figure 12](#). The gain of detectors is modulated by an oscillator frequency, f_{osc} , slightly different from the laser pulse or modulation frequency, f_{laser} . The phase shift and the amplitude of the fluorescence signal then transfer into a signal at the difference frequency, $f_{laser} - f_{osc}$. This is the same ‘heterodyne’ principle that is used in a radio. The advantage is that the difference frequency can be made independent of and much

Figure 12 Frequency-domain FLIM by laser scanning and modulated point-detectors.

lower than the laser frequency. The phase and the amplitude are determined at the difference frequency where filtering and signal processing can be performed by digital techniques ([Gratton and Barbieri, 1986](#)).

Both the modulation of the excitation light and the modulation of the detectors need not necessarily be sinusoidal. Frequency-domain systems can therefore also be used with high-frequency pulsed lasers ([Gratton and Barbieri, 1986](#)).

Frequency-domain FLIM treats the fluorescence signal as an analog waveform, not as individual photon detection events. It is therefore able to work at extremely high intensities, where single-photon detection becomes impossible. Problems may occur at extremely low intensities, when the detector, on average, delivers less than one photon within the time interval of the phase calculation. What happens in this situation depends on the details of the electronics used.

The photon efficiency of frequency-domain FLIM depends on a number of instrumental details. The efficiency increases with the modulation degree in the excitation light source and in the detectors. The best efficiency is obtained by using short laser pulses and modulating the detectors by square-wave signals. Details can be found in [Philip and Carlsson \(2003\)](#).

Frequency-domain FLIM by modulated image intensifiers

Detection of frequency-domain FLIM data is possible by wide-field excitation and a gain-modulated camera ([Lakowicz and Berndt, 1991](#)). The electronic principle is shown in [Figure 13](#). An image intensifier is gain-modulated at a frequency slightly different from the modulation frequency of the laser. A series of images for different times in the period of the difference frequency is taken, from which the phase and the modulation degree are calculated. Alternatively, the phase of the camera modulation can be changed incrementally, and several images for different phase recorded.

FLIM Data Analysis

Time-domain data

Time-domain FLIM data (from TCSPC FLIM systems or gated camera systems) are arrays of pixels each of which contain photon numbers in a (usually large) number of time channels,

see Figure 14, middle. To obtain fluorescence decay parameters from such data an iterative convolution procedure is used. The function of a suitable decay model is convoluted with the instrument response function (IRF). The IRF is the response of the detection system to the excitation pulse itself. It is either measured or calculated from the fluorescence decay data. The fit procedure then optimizes the model parameters until the best fit to the photon numbers in the time channels is achieved.

Usually the decay profiles are modeled by sums of two or three exponential functions. These models are described by several decay times and amplitude coefficients. The final FLIM image is obtained by assigning the brightness to the total photon number in the pixel, and the color to a selected decay parameter (Figure 14, right). This can be the lifetime of a single-exponential decay, an amplitude- or intensity-weighted average of the lifetimes in a multi-exponential decay, or a lifetime or amplitude ratio.

Frequency-domain data

Frequency-Domain data contain two numbers in each pixel: a phase and a modulation degree. Such data can be analyzed elegantly by the 'Phasor' approach (Digman *et al.*, 2008). Phasor analysis does not explicitly aim on determining fluorescence lifetimes or decay components for the pixels. Instead, it uses the phase and the modulation degree directly. For each pixel, a pointer (the phasor) is defined and displayed in a polar plot. The phase is used as the angle of the pointer, the modulation degree as the amplitude. The phasors of pixels with single-exponential decay profiles end on a semicircle.

Figure 13 Frequency-domain FLIM by wide-field excitation and modulated image intensifier.

Phasors of pixels with multi-exponential decay profiles, i.e., sums of several decay components, end inside the semicircle.

Pixels with different signature in the phasor plot are back-annotated in the image by giving them different colors. An example is shown in Figure 15. It shows a phasor plot for several cells, B–F, shown at the top of the figure. The cells were transfected with different fluorescent proteins. (F) is an untransfected cell. As can be seen in the lower part of the figure, the fluorophores form different spots in the phasor plot, as does the autofluorescence of the untransfected cell.

Phasor analysis is not restricted to data obtained in frequency-domain systems. It can be applied to Fourier-transformed time-domain data as well (Digman *et al.*, 2008).

Latest Developments

In the last ten years, FLIM techniques have made impressive progress. The most obvious one is in the spatial

Figure 15 Phasor analysis. Five different cells, transfected with (B) YFP, (C) paxillin-CFP, (D) EGFP, and (E) RAICRU-Rac1. (F) is an untransfected cell emitting only autofluorescence. Figure 14 Time-domain FLIM data analysis.

resolution: early FLIM images were recorded with no more than 128×128 pixels. The reasons were low efficiency of the optical systems and detectors, and limitations in available memory size. Within the past ten years, the efficiency of the detection path of laser scanning microscopes has improved significantly. In TCSPC FLIM, conventional PMTs have been replaced with single-photon avalanche photodiodes and hybrid detectors. These detectors have considerably higher detection efficiency than conventional PMTs. Hybrid detectors also deliver cleaner signals (Becker *et al.*, 2011a). Thus, they not only detect more photons, but also allow the FLIM system to achieve a higher lifetime accuracy for a given number of photons.

The speed and memory size of computers has increased by more than an order of magnitude. As a result, the raw data (e.g., data for single photons) can be transferred directly into the computer and the FLIM data be built up in the computer memory. With the introduction of 64-bit operating systems memory size is no longer a problem. FLIM data can therefore be recorded at mega-pixel resolution. For example, TCSPC FLIM data have been recorded with a spatial resolution of 2048×2048 pixels, and with 256 time channels in each pixel. The total data size of one of these images is more than 2 GB (Studier and Becker, 2014).

Increased efficiency helps avoid artifacts induced by photobleaching, photodamage, or by photo-induced metabolic changes in the samples. As a result, FLIM can now be combined with multidimensional microscopy techniques, such as Z-stack imaging, time-series recording, mosaic imaging (Studier and Becker, 2014; Becker, 2015a,b), or excitation-wavelength scanning. Lasers of different wavelength can also be multiplexed at high rate, and lifetime images for several combinations of excitation and emission wavelength be recorded quasi-simultaneously (Becker, 2015a). The wavelength range of FLIM has recently been extended into the near infrared. The titanium-sapphire laser of a multiphoton microscope is used as a one-photon excitation source, and the fluorescence is detected by an NIR-sensitive hybrid detector (Becker and Shcheslavskiy, 2013).

FLIM, especially TCSPC FLIM, has been combined with STED (stimulated emission-depletion) microscopy (Auksorius *et al.*, 2008; Bückers *et al.*, 2011; Lesoine *et al.*, 2012) and with NSOM (near-field scanning optical microscopy) (Cadby *et al.*, 2005; Gaiduk *et al.*, 2007; Micic *et al.*, 2004) to obtain fluorescence lifetime images with optical super-resolution.

Instruments based on a combination of confocal or two-photon laser-scanning microscopes with TCSPC are, in principle, able to record also fluorescence correlation (FCS). In the early times of FLIM FCS was often prevented by low detection efficiency or the inability of the scanner to stop the beam in a defined spot. These problems have been solved by now so that almost any TCSPC FLIM system is able to record FCS. FCS measurement can be combined with fluorescence decay data to improve the separation between different fluorophores (Böhmer *et al.*, 2002; Anthony and Berland, 2013). FCS data can also be derived from scan data by RICS (raster image correlation spectroscopy) (Digman *et al.*, 2005).

TCSPC FLIM has been extended to simultaneously record fluorescence (FLIM) and PLIM (Becker *et al.*, 2011b; Becker, 2015a). This opens a way to determine oxygen concentrations

in cells and tissue and simultaneously obtain metabolic information via the fluorescence decay of NADH.

Progress has also been made in recording dynamic effects in the fluorescence lifetime of biological systems. With faster data recording and processing rates available, FLIM data can be acquired at a speed limited only by the maximum exposure the sample tolerates. Even TCSPC FLIM, which is usually considered slow in acquisition speed, delivers image rates of one image per second (Katsoulidou *et al.*, 2007). A technique to record extremely fast lifetime changes by TCSPC is based on the buildup of a photon distribution over the distance along a line scan, the arrival times of the photons after the laser pulse, and the arrival times after a periodic stimulation of the sample. The technique is called Fluorescence Lifetime-Transient Scanning (FLITS) and has been shown to record photochemical and non-photochemical chlorophyll transients in plants and transient changes in the Ca^{2+} concentration in cultured neurons (Becker *et al.*, 2014; Becker, 2015b).

Introduction

Fluorescence microscopy has long been the standard for cellular imaging. Its great advantage lies in its high specificity, which allows discriminate imaging of organelles and ensembles of specific proteins. The relatively recent ability to observe individual fluorescing molecules in living cells results from the convergence of innovative molecular labeling techniques and highly sensitive and fast imaging instruments. Indeed, through the culmination of these technological advances, researchers are now able to directly observe the dynamics and instantaneous distributions of single molecules of cellular systems. Moreover, these techniques offer the ability to study low-affinity, weak interactions that may otherwise be inaccessible with conventional biochemical techniques. The single-molecule imaging techniques described in this section have provided great insight into a host of cellular events, not limited to molecular target-searching, protein-scaffold interactions, and virus trafficking (Kusumi *et al.*, 2014; Ruthardt *et al.*, 2011; Levi and Gratton, 2007).

Conventionally, fluorescently labeled molecules may be imaged in an ensemble mode, in which captured images are the combination of the light emanating from all labeled molecules instantaneously. To image individual molecules, however, two accommodations are needed. First, the type of fluorescent label and its optical concentration must be selected judiciously. Second, a proper spatiotemporal resolution needs to be specified as determined by image acquisition and optical parameters.

The fundamental physical concept for imaging single molecules is the optical diffraction limit, first described by Abbe (1873):

$$d = \frac{\lambda}{2NA}$$

where d is the effective resolution, λ is the wavelength of emitted light, and NA is the numerical aperture of the imaging objective lens. This equation describes the minimal perceivable spatial resolution in a conventional optical imaging system. In the context of optical fluorescence imaging (for which the NA is typically ~ 1.3 – 1.4) this limit corresponds to roughly ~ 250 nm in practice. Furthermore, camera detectors that capture fluorescence emission events are discretized by pixels whose effective size is made to correspond to roughly half the diffraction limit. This signifies that any focused individually fluorescing molecule small enough to be considered a point source will appear as a discretized 250 nm diameter spot.

Localization microscopy (LM) comprises the experimental and computational techniques that permit the determination of the spatial coordinates of individual fluorescing molecules with high precision. Single-particle tracking (SPT) is a subfield of LM, which involves reconstructing single-molecule trajectories from sequential localization events in live cells.

In this article, the principles of LM will be overviewed, leading to a discussion of high-speed LM and SPT. Emphasis will be placed on the types of information these techniques yield and how they may contribute to the understanding of cellular processes.

The Localization Concept

The shape of light emitted from a single diffraction-limited fluorescing molecule is described by the point spread function (PSF). Consistent with the Abbe diffraction limit, the PSF has an approximately isotropic Gaussian profile in the lateral dimensions. The captured raw image of an emitting single molecule is therefore the intensity profile projected onto a pixelated detector array (e.g., a highly sensitive camera). This profile, in turn, may be numerically fitted by a two-dimensional (2D) Gaussian function, whose localization precision is inversely proportional to the square root of the number of photons captured from the PSF (Thompson *et al.*, 2002; Mortensen *et al.*, 2010). The 'localization' of the PSF in this manner provides a localization precision improvement by roughly an order of magnitude over the diffraction limit. This remark implies that LM may be used as a super-resolution microscopy technique; a sufficient density of localizations allows pointillist image reconstructions at sub-50 nm resolution.

Two major applications have emerged based on this form of microscopy: super-resolution LM and SPT. Early studies reported the use of functionalized quantum dots, beads, and dyes for localization (Pinaud *et al.*, 2010). Due to their long fluorescence lifetimes and narrow emission spectra, these probes remain strong candidates for LM studies, in particular for tracking. The main impediment for these types of exogenous markers is that they are often limited to studies of the cell membrane in which sampling of the surface is sparse.

Many studies in LM employ specialized fluorescent probes that are capable of stochastic activation. Under this configuration, only a small subpopulation of probes emits light in the image capture interval (typically of the order of tens of milliseconds). Probes that may be used in this fashion include the classes of photoactivatable, photoswitchable, and photoconvertible fluorescent proteins and dyes. Stochastic emission density is modulated by an activation illumination, which is used in conjunction with the read-out excitation illumination. These sparse emission events are captured in consecutive image frames, upon which their precise spatial coordinates are determined by fitting their PSF. Accumulation of these coordinates over a few thousand image frames eventually forms a pointillist reconstruction of the probe distribution inside the cell (Figure 1). Many freely available software packages are currently available for localization and visualization of PSFs from raw image acquisitions (Small and Stahlheber, 2014).

LM performed on fixed cells is possible with immuno-fluorescent labeling with the use of stochastically emitting

Figure 1 Sequence flow for LM in a live cell (over four image frames). Imaged are transmembrane domain proteins with an extracellular photoactivatable Dendra2 protein. (a) In the top row, multiple images with sparse fluorescent emissions are acquired. In the bottom row, corresponding localizations are shown. The color code corresponds to the images acquired at times t_1 through t_4 . (b) A reconstruction of the localizations is displayed by overlaying all the localizations from (a). The color code is conserved, and the individual spot sizes correspond to the approximate localization precision. (c) Localizations in sequential frames are connected together to form single-molecule trajectories (the color code corresponds to individualized trajectories).

Table 1 Different fluorescent probes used in LM and their relative properties

Probe	Size (nm)	Brightness	Lifetime
Fluorescent proteins	10–20	Low	Short
Fluorescent dyes	0.5–10	Medium–high	Medium
Nanoparticles	20–50	Medium–high	Long
Fluorescent beads	5–1000	High	Long
Quantum dots	10–20	High	Long

fluorescent dyes. Stochastic optical reconstruction microscopy (STORM) belong to a class of techniques that takes advantage of this approach and has been responsible for providing detailed images of intracellular organelles as well as insight to protein distributions, and morphologies of biological complexes (Rust *et al.*, 2006). With bright fluorescent dyes, localization precisions can reach sub-20 nm levels. Variants of the STORM technique include the possibility of imaging in live cells (Jones *et al.*, 2011).

Photoactivated localization microscopy (PALM) involves transgenically expressing photoactivatable fluorescent proteins for LM (Betzig *et al.*, 2006). As fluorescent proteins are not nearly as bright as synthetic dyes, PALM generally suffers from a weaker signal-to-noise ratio for single-molecule detections. However, it is less vulnerable to redundant localizations and is more amenable to live-cell imaging compared to STORM. Table 1 summarizes the properties of the most commonly used types of fluorescent probes used in LM.

There are persistent issues in LM, most of which can be addressed through post-processing steps. The first issue is that of false-positive detections. Inevitably, noise may be mischaracterized as an emitting probe during numerical localization. Many localization tools attempt to filter out these effects (e.g., by using a Gaussian filter), although it is often necessary to manually adjust localization tolerances as a function of the signal-to-noise ratio of the typical PSF. Second, many localization events may emanate from the same molecular target in consecutive image frames. This is prevalent

when photoswitchable probes are used but in the most general case it arises due to a mismatch between image integration time and the probe ‘on-time.’ As will be discussed, for high-speed LM and SPT, these are not necessarily drawbacks. Third, faithful reconstruction of imaged probes demands a mechanically stable imaging apparatus, as a drift over the course of an acquisition may easily surpass 100 nm. To address this challenge, piezo stages with closed-loop feedback controls can negate stage drift effects. The most accessible approach, however, is the use of fiduciary markers, such as diffraction-limited sized beads, which may be used to correct for stage drift after imaging. Finally, there is a fundamental relationship between localization density (which is dependent on the duration of the acquisition) and the resolution of final pointillist reconstruction that must not be overlooked. Effectively, this is a trade-off between temporal and spatial resolution; the smaller the feature size, the more time is required for imaging (Shroff *et al.*, 2008).

Experimental Requirements

LM typically involves the use of an inverted fluorescence microscope with multiple laser light sources (Figure 2). The relatively small number of photons emitted from individual fluorescent probes demands the use of both high-NA oil-immersion objective lenses (typically 60x or 100x magnification) and sensitive electron multiplying charge coupled device (EMCCD) cameras. To ensure that cells remain relatively unperturbed during experimentation, both the stage on which the sample is mounted and the imaging objective lens are heated to roughly 37 °C. Chambers to control levels of CO₂ and the humidity are also commonly used, especially for long duration experiments.

Wide-field (WF) microscopy is the simplest way of performing LM. Laser light is focused in the back focal plane (BFP) of the imaging objective to collimate light propagating toward the sample. Due to the short exposure times needed for LM, high laser powers of the order of 0.1–1 kW cm^{−2} at the

Figure 2 Schematic of the typical experimental setup used in SPT and high-speed LM microscopy. Laser lines are selected with an acousto-optic tunable filter (AOTF), the output of which is coupled into a multimode fiber. The output of the fiber is collimated and subsequently focused to the BFP of the high-NA objective lens. A mirror on a translation stage may be used to switch between WF and TIRF modes of illumination. The objective lens serves to illuminate the sample with excitation light and to capture resulting emission light, after which it passes through an emission filter before being imaged by EMCCD.

sample are required. Finally, effective pixel sizes are made to conform to the spatial Nyquist sampling criterion for a diffraction-limited spot (i.e., roughly ~ 120 nm).

Total internal reflection fluorescence (TIRF) microscopy is a popular configuration for LM. It involves focusing the excitation laser in the objective BFP at a position shifted from the optical axis. As a result, the excitation beam reaches the coverslip at an angle. When this incidence angle is sufficiently large, the laser beam is not transmitted but reflected by the coverslip, except for an evanescent field extending roughly ~ 200 nm in depth that illuminates only the region of the cell immediately adjacent to the coverglass. The consequence of this type of excitation is the suppression of background cytosolic signal, greatly enhancing the signal-to-noise ratio of imaged fluorophores.

High-Speed LM

The principle of high-speed LM is to capture successive super-resolution ‘snapshots’ of molecular targets inside a live cell. This type of imaging modality permits monitoring of dynamics of cellular complexes at the single-molecule level. More specifically, it offers the potential to monitor molecular assemblies that drive cellular processes in physiological conditions.

Both PALM and STORM may be used in this configuration, although distinct tradeoffs exist, as discussed in Section ‘The Localization Concept.’ Bright fluorescent dyes may be used for imaging structures on the outside of the cell membrane, however, imaging inside the cell requires intrusive techniques. Imaging inside the cell is greatly simplified through the use of

transgenically expressed fluorescent proteins. For this reason, PALM is a less restrictive choice for high-speed LM.

From the outset, however, there are significant challenges with high-speed LM. The dynamic environment of a live cell limits what targets may be imaged and accurately reconstructed. Desired targets must be chosen such that they remain relatively immobilized in the duration of image acquisition, which may last 25–60 s for a proper reconstruction snapshot (Shroff *et al.*, 2008). For example, cytosolic structures may be exceedingly difficult to image, while membrane rafts may prove a more amenable target. This leads to a second difficulty: a sufficient number of frames must be captured to ensure a proper localization density for super-resolution reconstruction. The judicious choice of bright probes and short acquisition times may alleviate the time required for acquisition. As imaging occurs intermittently over many intervals, the reserve of unbleached probes may eventually be depleted. Moreover, this implies that a loss of localization density (and subsequent resolution) over the course of an acquisition is to be expected in high-speed LM.

In practice, high-speed LM has been prevalently used in studies of membrane organization (in TIRF mode). The technique has also notably been used to monitor clustering events within cells and the nucleus, such as the formation of RNA polymerase II in human cells (in WF configuration) (Cisse *et al.*, 2013). Figure 3 shows changes in the actin distribution of a synaptic spine in the hippocampal neuron of a live rat after the activation of glutamate receptors (Izeddin *et al.*, 2011). In contrast to diffraction-limited imaging, this application reveals nanoscopic morphological differences over time.

STORM microscopy can also be made compatible with high-speed LM through the use of bright photoswitchable dyes

Figure 3 Structural dynamics of a synaptic spine visualized using high-speed LM in PALM mode (Izeddin *et al.*, 2011). Upper panels: super-resolution reconstruction of actin (ABP-EosFP construct) of a single spine at differently spaced time intervals. The spine head shrinks upon pharmacological application of the glutamate receptor agonist α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPA). Bottom panels: corresponding raw image projections of frames used for super-resolution reconstruction.

and genetic fusion methods. Here, functionalized fluorescent dyes may be coupled with antibodies and bind to individual ligands at the cell membrane for imaging. For intracellular tagging, dyes may be functionalized and delivered inside the cell to bind to intracellularly expressed tags (e.g., SNAP tags or Halo tags). If photoswitchable dyes are used, there is the advantage that identical molecules may be monitored in successive super-resolution ‘snapshots.’ The higher brightness of dyes relative to fluorescent proteins also shortens the acquisition time required between snapshot intervals (Jones *et al.*, 2011).

SPT

Throughout the cell, the environment in which a single molecule translocates is generally highly heterogeneous and complex. Single-molecule motion may be affected by protein–protein and cytoskeletal interactions, but may also be influenced by active transport processes. SPT permits these events to be captured as they happen. As a subcategory of LM, SPT follows the same imaging and localization workflow, however with an additional step, that involves tracking of individual molecules based on their spatiotemporal coordinates (Saxton, 1993).

In comparison to diffraction-limited methods that measure molecule dynamics (such as fluorescence recovery after photobleaching microscopy) or molecule transiting events in confocal volumes (as in fluorescence correlation spectroscopy), SPT allows observation of different types of motion for the same molecule. Moreover, SPT has provided compelling evidence supporting the view that single molecules regulate cellular functions via a relentless ‘interplay’ between random motion and molecular interactions (Kusumi *et al.*, 2014).

There are a variety of probes that can be used for tracking single molecules in living cells. For example, long individual trajectories spanning hundreds of image frames may be acquired through the use of photostable-functionalized quantum dots (Dahan *et al.*, 2003). Fluorescent dyes may also be

coupled to ligands (e.g., antibodies or nanobodies) and bound to targets at the cell membrane to capture long and rich trajectories (Giannone *et al.*, 2010). Targets inside the cytoplasm, however, are difficult to reach with external fluorescent probes. Common approaches to introduce probes inside the cell may include microinjection, electroporation, and using fusogenic liposomes to transport probes inside the cell.

Single-particle tracking PALM (sptPALM) is a manner of tracking transgenically expressed photoactivatable fluorescent proteins (Manley *et al.*, 2008). Trajectories in this configuration are generally short, spanning only a few frames before fluorescence bleaching. The weak fluorescence signal of fluorescent proteins constitute another limitation for the applications of sptPALM. However, statistical techniques that consider only trajectory translocations (and not full-length trajectories) may stand to benefit from the high-density nature of sptPALM data.

SPT in many cases is a nontrivial and computationally expensive problem. A contributor to this difficulty is in cases of high localization density, which may render assignment of a specific localization to a given trajectory unclear. This task is additionally hampered when trajectories cross and when probes are prone to blinking. Finally, the diffusivity for the same tracked molecule may vary by orders of magnitude over distances as short as ~ 100 nm within the cell. Most tracking algorithms require an initial estimate of the diffusivity of the tracked species to evaluate the most probable connections between frames. For this reason, tracking of distinct diffusive populations of the same molecule imposes a challenge for single-molecule tracking. A result of the aforementioned challenges is that most high-density SPT methods are based on probabilistic notions of point connections within a trajectory, instead of simple nearest-neighbor approaches. A recent review describes in detail the performance of many commonly used tracking algorithms (Chenouard *et al.*, 2014).

Traditionally, trajectories may be analyzed by plotting how far a particle has traveled within a given time period. A plot of the mean square displacement (MSD) against the time period describes this relation and is commonly used to study single-particle trajectories, as described in Figure 4 and Table 2.

Figure 4 MSD against time lag divided by time step plots illustrating different types of motion observed in single-particle trajectories. The random diffusive trace is overlaid in blue on all plots.

Table 2 Different models of motion based on the mean square displacement where $X^2(\tau)$ is the lag time-dependent mean square displacement, τ is the lag time, D_{2D} is the 2D diffusion coefficient, α is the anomalous exponent, v is the magnitude of the particle velocity, R^2 is the size of the confinement area, and A_1 and A_2 are constants determined by the confinement geometry

Motion	Model	Possible explanations	References
Random diffusion	$X^2(\tau) = 4D_{2D}\tau$	Homogeneous environment	Saxton (1997)
Confined motion	$X^2(\tau) = R^2 \left(1 - A_1 e^{-A_2 \frac{4D_{2D}\tau}{R^2}} \right)$	Binding events Trapped particles Corralling Transient binding	Saxton and Jacobson (1997)
Anomalous diffusion	$X^2(\tau) = 4D_{2D}\tau^\alpha$	Hopping diffusion Obstacle presence	Feder <i>et al.</i> (1996)
Directed motion	$X^2(\tau) = 4D_{2D}\tau + (v\tau)^2$	Active/motor transport	Saxton (1994)

For purely diffusive (Brownian) motion where particle movement is due entirely to thermal agitations, this relationship is linear. In fact, a diffusion coefficient for a given trajectory can be estimated by taking the slope of this relation. For many biomolecules measured *in situ*, however, MSD relations are not linear for a variety of reasons. The media in which biomolecules are tracked are generally highly heterogeneous in composition and highly dynamic in their behavior. For example, tracked membrane proteins may interact with the actin cytoskeleton, focal adhesion points, or may undergo endocytosis. The diversity of models that exist to describe the cell membrane further justifies the consensus that the medium in which membrane proteins translocate is not homogeneous (Saxton and Jacobson, 1997). Theoretical expressions have been derived to describe different types of motion and how they may relate to these trends. Table 2 gives a summary of

these types of models of single-particle motion in the case of 2D trajectories.

Confined motion refers to cases in which a particle is immobilized within a certain region throughout the acquisition period. This may be the consequence of a binding event, such as a receptor becoming trapped in a lipid raft on the cell membrane, or due to the corralling of cytoskeletal polymers. A few ways of modeling confined trajectories have been proposed; in Table 2 we present the case for a circular 2D confinement area of size R^2 (Saxton and Jacobson, 1997).

Directed or active motion refers to cases where a tracked particle has a directional bias in a certain direction. This type of motion is regularly reported in actin- and microtubule-dependent active transport in the cytoplasm (Yildiz *et al.*, 2003).

Geometric effects additionally play an important role in the motion of single molecules. In environments such as the

Figure 5 (a) Simulated trajectories with identical diffusion characteristics in the presence of a potential well. (b) In black, the MSD is plotted against the time lag (τ) divided by the time step (Δt) and demonstrates a trend consistent with that of a confined trajectory. In blue, the MSD of the purely random diffusive case without potential well. (c) Through spatial meshing and statistical inference, the interaction energy and directional bias of the trajectories may be resolved. The time step between trajectory points is 25 ms.

nucleus, there is evidence that the space explored by diffusing molecules possesses a fractal organization (Bancaud *et al.*, 2012). In this situation, obstacles at many different spatial scales affect the motion of diffusing molecules, resulting in an anomalous description of the motion. This type of behavior has been reported for transcription factors inside the nucleus (Récamiér *et al.*, 2014).

Additional effects on the MSD include the nonnegligible errors in localization of trajectory points. Acquisition times should generally be chosen such that tracked molecule displacements are greater than the localization precision. However, acquisition times greater than the characteristic time of molecule translocations may give rise to inaccurate estimates of the diffusivity (Montiel *et al.*, 2006). Nonetheless, altering the image acquisition time may permit observation of different diffusive populations.

MSD-based analysis may be subject to a number of drawbacks in a variety of contexts. First, it is particularly sensitive to noise, which may overestimate actual diffusion coefficients (Montiel *et al.*, 2006). Next, MSD values for large lag times are calculated with less data, hindering their accuracy. It is a common convention to calculate the MSD over τ values spanning less than 25% of the trajectory and measure the slope between the 2nd and 5th time lag to estimate a diffusion coefficient (Saxton and Jacobson, 1997). In the case of sptPALM, for example, trajectories are generally short (less than 10 translocation) and subject to position noise of the order of 30–50 nm. The net effect of these characteristics is a poor estimation of the MSD and, as a consequence, of the diffusion coefficient. Finally, while MSD plots may postulate an interaction via the presence of a trapping energy, there is no robust manner to extract information about the nature and strength of this type of interaction. Moreover, MSD analysis ostensibly models biomolecule motion as Brownian, upon which only deviations inform about the presence of an interaction.

Recent approaches have been introduced that rely on spatially partitioning the area explored by trajectories, and generating maps of the dynamics that describe the motion of tracked molecules (Masson *et al.*, 2009, 2013; Türkcan *et al.*, 2012). Such techniques are particularly well suited for

high-density trajectory data (such as in sptPALM) that invite the use of powerful statistical methods. The principle, in this case, is to infer a probability distribution for a dynamic parameter. The model of motion for the trajectory is chosen to account not only for the diffusion but also a possible interaction energy, which is systematically neglected in most MSD-based analyses. With this type of modeling, binding to molecular partners, crowding effects, and electrostatic interactions between molecules can be distinguished. Furthermore, an important advantage to this particular approach is that there is no restriction on the trajectory length. In other words, many short trajectories are statistically equivalent to a single long trajectory. Figure 5 shows how MSD analysis can evidence the presence of a potential energy trap for simulated confined trajectories. By using a statistical inference-based technique, the strength of the trap (as well as the directional bias it imposes) can be revealed and mapped with high accuracy and precision.

An important notion in SPT is that individual molecules switch between specific ‘states’ of motion at different moments in time. This may be the case of a molecule transitioning between an immobilized state (e.g., when bound to a scaffold) and a freely diffusing (unbound) state. This type of analysis requires tools that depart from typical MSD analysis that broadly categorizes trajectories (Figure 4). Specifically, this state description of single-molecule motion can be achieved by using a hidden Markov model (HMM) (Das *et al.*, 2009; Persson *et al.*, 2013). The HMM calculates the probability of a molecule assuming a state at a given time and may also be used to calculate transition rates between states to estimate molecular reaction kinetics.

Future Trends/Avenues

Single-molecule imaging garners significant interest in biological studies. The two methods discussed, high-speed LM and SPT, are critical tools in the study of modern cell biology and will benefit from new microscopy methods and data treatment methodologies in the future.

With regard to microscopy, progress is being made in three-dimensional (3D) single-particle imaging (Hajj *et al.*, 2014). Astigmatic imaging (Kao and Verkman, 1994), light-sheet microscopy (Chen *et al.*, 2014), adaptive optics (Izeddin *et al.*, 2012), biplane (Ram *et al.*, 2008) and multi-focus microscopy (Abrahamsson *et al.*, 2013) have already been used to this end. These techniques have the benefit of being able to capture the full range of motion of single molecules inside the cell, whereas 2D techniques are often limited to observing events on the membrane in TIRF mode illumination mode.

High-density SPT is of great interest, as the massive data it yields justifies the use of powerful statistical techniques for understanding whole-cell single-molecule dynamics with high spatial resolutions. Related, correlative studies with single-molecule imaging and observing gross cellular behavior will grant insight into the molecular basis of many cellular activities, such as polarization, mechanics, and migration.

The study of cell biology is inherently related to interactions between different types of molecules within the cell. To this end, multicolor SPT and high-density LM techniques permit the observation of interactions between different populations of molecules (Kapanidis *et al.*, 2004). It is worth noting, however, that this form of imaging is most amenable when fluorophores of narrow emission spectra are used (such as quantum dots) to avoid spectral mixing between channels.

On the data treatment end, much of the development in single-molecule research comes from techniques borrowed from statistical physics. Statistical inference methods, for example, enable mapping of the physical parameters that dictate particle motion. The application of HMMs to single-particle trajectories is also an important advance, and will further reinforce insight into the multiscale nature of diffusive processes inside the cell.

Conclusion

The introduction of single-molecule imaging in cellular biology has resulted in a paradigm shift in the way biological processes are understood (Ha, 2014). Applied to living cells, high-speed LM provides insight into the temporal evolution of biological complexes with nanoscale resolutions. SPT, in contrast, reveals unprecedented information of the environment experienced by individual biomolecules. Collectively, these are important tools that may be applied to a wide range of problems faced in modern cell biology.

Intravital Microscopy in Mammalian Organisms: From Tissue Physiology to Cell Biology

R Weigert, National Institutes of Health, Bethesda, MD, USA

© 2016 Elsevier Inc. All rights reserved.

Brief Historical Background on Intravital Microscopy

Since the development of the first optical microscope in the late 1500s, biologists have been intrigued by the idea of imaging the dynamics of biological processes in live organisms. The first example of intravital microscopy (IVM) in a living animal is dated 1839, when Rudolph Wagner described the interaction of leukocytes with the walls of blood vessels in the webbed feet of a live frog by using bright field transillumination (Wagner, 1839). Since then, this approach has been extensively used particularly in thin transparent tissue to study vascular biology (Clark and Clark, 1932; Irwin and Macdonald, 1953; Zweifel, 1954) or cell migration (Thorogood and Wood, 1987; Wood and Thorogood, 1984). A major step forward in IVM came with the development of epifluorescence microscopy which enabled more detailed investigations of the dynamics of individual cells in the circulation (Nuttall, 1987), in tumors (MacDonald *et al.*, 1992), or in the immune system (von Andrian, 1996), and with the introduction of the confocal microscope, which has made possible to collect serial optical sections from a given specimen, thus significantly increasing the spatial resolution (Jester *et al.*, 1991; O'Rourke and Fraser, 1990; Villringer *et al.*, 1989). The main limitation of these techniques has been tissue light scattering, which limits imaging to either transparent tissue in small organisms or up to a few microns below the surface of mammalian organs. We had to wait for the early 1990s to extend the range of observations to deep tissue, thanks to the development of multiphoton microscopy (MPM) by the Webb's lab (Denk *et al.*, 1990; Zipfel *et al.*, 2003b). Initially, this technique was used in the neurosciences (Svoboda and Yasuda, 2006), and only later extended to other areas such as immunology and cancer biology (Amornphimoltham *et al.*, 2011; Pittet and Weissleder, 2011; Weigert *et al.*, 2010). Finally, in the last decade the development of strategies to minimize the motion artifacts due to the heartbeat and respiration has made possible to successfully image subcellular structures with spatial and temporal resolution comparable to those achieved in *in vitro* model systems, thus opening the door to the use of IVM to study cell biology (Weigert *et al.*, 2013).

Imaging Techniques Used to Perform IVM

IVM is performed primarily using laser-scanning confocal and MPM. Confocal microscopy is a well-established technique that is based on single photon excitation (Figure 1(a)), and relies on lasers emitting in the UV-visible range, as a light source for the excitation of the specimen. This technique uses pinholes to select the emitted light generated from a specific optical section, thus enhancing the spatial resolution and enabling the visualization of small structures in the submicron

range (Wilson, 2002). However, due to the high scattering of UV-visible light in biological samples, confocal microscopy can be used to samples up to 80–100 μm in depth (Figure 1(a); Masedunskas *et al.*, 2012a). Moreover, confocal microscopy is not suitable for long-term imaging (more than 30–60 min) due to out-of-focus photo-damage and photo-bleaching that may generate a pathological tissue response due to increased oxidative stress.

MPM is one of the nonlinear optical microscopy techniques that are based on generating contrast by higher-order interactions between light and the biological specimen, which involve the absorption or the scattering and recombination of two or more photons (Campagnola and Loew, 2003; Helmchen and Denk, 2005; Mertz, 2004; Oheim *et al.*, 2006; Rubart, 2004; Stutzmann and Parker, 2005; Svoboda and Yasuda, 2006; Zipfel *et al.*, 2003b; Figure 1(b)). The first multiphoton microscope (Denk *et al.*, 1990) was based on the principle of two-photon excitation postulated by Maria Goeppert-Mayer in her PhD thesis (Göppert-Mayer, 1931). Multiphoton excitation is based on the fact that a molecule of a fluorophore can be excited by the almost simultaneous absorption (within atto- or femto-seconds) of two (three) photons that have half (one-third) of the energy that is required to fill the gap between two of its energetic levels (Figure 1(b); Helmchen and Denk, 2005; Zipfel *et al.*, 2003b). This is achieved by using lasers that emit near-infrared/infrared (NIR/IR) light (from 690 to 1600 nm) in very short pulses (in the order of 100 fs) at high-repetition rates (80–100 MHz), and by using high numerical aperture lenses that focus the light to the excitation spot. In ideal conditions multiphoton absorption occurs in a very small volume (1 fl) (Helmchen and Denk, 2005; Zipfel *et al.*, 2003b). This results in the absence of off-focus emissions, thus eliminating the need for a pinhole and reducing significantly both photo-toxicity and photo-bleaching. Moreover, since NIR/IR light has a lower tissue scattering (i.e., deeper tissue penetration) than UV or visible light (Theer and Denk, 2006), MPM can resolve structures up to a depth of 300–500 μm in most of the tissues, and up to 1–1.5 mm in the brain (Masedunskas *et al.*, 2012a; Theer *et al.*, 2003).

Other nonlinear optical techniques have been used for IVM, and among them second harmonic generation (SHG) and third harmonic generation (THG), two processes that do not involve energy absorption since the incident photons are recombined into a single photon of a higher energy in a process without energy loss (Figure 1(c)). For this reason, they are suitable for imaging biological specimen with even lower photo-toxicity than MPM (Campagnola and Loew, 2003). Although the harmonic signals are produced in the forward direction and thus more suited for imaging slices, the backward scattering signal is still sufficient to generate details about the tissue architecture. Second harmonic signals are generated by specific molecules that are assembled in highly ordered

Figure 1 Fluorescent light microscopy imaging techniques used for IVM. (a) Confocal microscopy. In confocal microscopy a fluorophore absorbs a single photon with a wavelength in the UV-visible range of the spectrum (blue arrow). After a vibrational relaxation (orange curved arrow), a photon with a wavelength shifted toward the red is emitted (green arrow). In thick tissue, excitation and emission occur in a relative large volume around the focal plane (FP). The off-focus emissions are eliminated through a pinhole, and the signal from the FP is detected via a photomultiplier (PMT). Confocal microscopy enables imaging at a maximal depth to 80–100 μm . (b) Two- and three-photon microscopy. In this process, a fluorophore absorbs almost simultaneously two or three photons that have half (red arrow) or a third (dark red arrow) of the energy required for its excitation with a single photon. Two or three photon excitation typically require near IR or IR light (from 690 to 1600 nm). Emission and excitation occur only at the FP in a restricted volume (1.5 fl) and for this reason a pinhole is not required. Two- and three-photon microscopy enable imaging routinely at a maximal depth of 300–500 μm . (c) SHG and THG. In SHG and THG, photons interact with the specimen and combine to form new photons that are emitted with twice or three times their initial energy without any energy loss. These processes have similar features to those described for two- and three-photon microscopy and enable imaging at a maximal depth of 200–400 μm . (d) A mouse engineered to express a membrane-targeted peptide fused to GFP (m-GFP) in keratin 14-expressing cells was injected with the nuclear dye Hoechst, and the tongue was imaged by either confocal or two-photon microscopy. A z-scan shows that nuclei (blue) can be imaged up to 100 μm (confocal) or 300 μm (two-photon). (e) In CARS microscopy two beams are used: the pump (ω_p) and the Stokes (ω_s). When they are tuned to match a vibrational energy gap (ω_{vib}), a strong anti-stokes signal is generated (ω_{CARS}). (f) In FLIM, a fluorophore is excited and the decay of the fluorescence emitted is measured. The lifetime τ is calculated based on $I(t) = I(0)e^{-t/\tau}$. Adapted from Weigert, R., 2014. structures, such as collagen fibers, microtubules, and muscle myosin (Campagnola and Loew, 2003; Zipfel *et al.*, 2003a; Zoumi *et al.*, 2002). On the other hand, third harmonic signals are generated at the interfaces between tissue components with different optical properties. For example, THG have been used to image lipid bodies in various living organisms (Debarre *et al.*, 2006) and to visualize myelin fibers during cancer invasion (Weigelin *et al.*, 2012). Both SHG and THG are often combined with MPM, thus expanding the repertoire of information that can be acquired (Weigelin *et al.*, 2012), and recently, up to six intrinsic signals coming from both multiphoton and harmonic emissions were resolved in the skin of live nude mice using spectral unmixing techniques (Radosevich *et al.*, 2008). Three other techniques have been recently used for IVM with very promising results: Coherent anti-Stokes Raman scattering (CARS), fluorescence lifetime imaging (FLIM), and optical frequency domain imaging (OFDI). CARS utilizes two combined laser beams to match the energy gap between two vibrational levels of the molecule of interest (Figure 1(d)). Similarly to THG, CARS has been used to image lipids and myelin fibers *in vivo* (Fu *et al.*, 2008; Le

et al., 2010; Muller and Zumbusch, 2007). FLIM measures the lifetime that a molecule spends in the excited state (Figure 1(e)). Since the lifetime depends on the characteristics of the environment, this approach provides quantitative information on cellular parameters such as pH, oxygen levels, ions concentration, and the metabolic state of various biomolecules (Bakker *et al.*, 2012; Levitt *et al.*, 2009; Provenzano *et al.*, 2009). OFDI is based on focusing a laser beam into the tissue and combining the light reflected across all depths with a reference beam. The analysis of the interference signal is utilized to derive the optical scattering properties enabling to determine structural information on the tissue (Vakoc *et al.*, 2009). OFDI ensures a deeper tissue penetration (1 mm), a faster acquisition time, and does not require any exogenous labeling, although it exhibits a lower spatial resolution when compared with MPM. Recently, a high-resolution three-dimensional analysis of the tumor microenvironment and its response to a targeted therapy has been reported in the absence of any exogenous labeling highlighting the enormous potential of this technique for diagnostic purposes and basic research (Vakoc *et al.*, 2009).

Current Applications of IVM

IVM is currently used in several areas of the biomedical field, which include physiology, neuroscience, immunology, tumor biology, stem cell biology, pathogen invasion, and cell biology. To properly illustrate the power of this approach the spatial resolution will be used as the main organizing criteria. First, the application of IVM to investigate the relationship between tissue architecture and function will be discussed; next, the developments in tracking individual cells and; finally, the most recent applications in studying the dynamics of subcellular structures *in vivo*.

Imaging Tissue Architecture and Function *In Vivo*

One of the main uses of IVM has been in the investigation of tissue response under both physiological and pathological conditions (Table 1). In this respect, the main advantage of this approach is the fact that various aspects of tissue physiopathology cannot be reconstituted in *in vitro* or *ex vivo* model systems (Weigert, 2014; Weigert *et al.*, 2013). The success of IVM in this arena has relied primarily on the availability and the development of a large series of tools and experimental approaches to contrast tissues *in vivo*. For example, tissue architecture has been highlighted by exploiting the fact that several endogenous molecules can be excited using either linear or nonlinear optical techniques (Zipfel *et al.*, 2003a; Figure 2(a)).

Among them is nicotinamide adenine dinucleotide (NADH), that emits in the visible range upon either single photon (360 nm) or two-photon excitation (710–760 nm). Although its two-photon cross section is very low, its abundance within the cell makes it a suitable endogenous label for both metabolic and structural studies (Figure 2(b)). Indeed, changes in the levels of NADH were measured in live mice during ischemia and reperfusion in the jejunum and the brain (Guan *et al.*, 2009), during microcirculatory failure in the liver (Paxian *et al.*, 2004) or in the kidney after lipopolysaccharide-induced sepsis (Wu *et al.*, 2007). These studies have provided novel insights on the acute and early changes in the metabolic state of tissues under various pathological conditions. Importantly, since NADH is distributed both in the cytoplasm and in the mitochondria, its emissions provide the contrast to highlight several details of the tissue architecture, thus

enabling the correlation between structure and metabolic activity. For example, in the brain, astrocytes can be distinguished from other cell populations based on the characteristic NADH pattern (Kasischke *et al.*, 2004); in skeletal muscles of both live animals and humans the architecture and the contractions of the sarcomere have been monitored in time-lapse modality by the NADH emissions from the mitochondria along the sarcomere Z-discs (Llewellyn *et al.*, 2008; Rothstein *et al.*, 2005); similarly, in the salivary glands of both live rats and mice, the architecture of the secretory acini and the fine details of the structure of the large ducts have also been imaged at a level of resolution almost comparable to that obtained by classical immunohistochemistry (Masedunskas and Weigert, 2008; Sramkova *et al.*, 2009; Figure 2(d)). Another molecule that has been extensively exploited for *in vivo* imaging is collagen, which generates a strong SHG signal when arranged in fibers (Campagnola and Loew, 2003; Zoumi *et al.*, 2002). In particular, detecting collagen has been extremely helpful in characterizing fibrotic tissues under various pathological conditions (Cox *et al.*, 2003; Megens *et al.*, 2007; Morishige *et al.*, 2006; Pena *et al.*, 2007; Schenke-Layland *et al.*, 2008; Figure 2(c)). Moreover, collagen fibers in live animals are a valuable reference point within the tissue, particularly in the context of tumor migration and invasion since they provide the means to correctly locate and orient tumors that are repeatedly imaged over long period of times (Brown *et al.*, 2003; Perentes *et al.*, 2009; Wyckoff *et al.*, 2007; see Figure 5).

Another approach to investigate tissue response *in vivo* is through the use of exogenously administered tracers. In particular, the vasculature is one of the main tissue components that have been visualized by IVM since it is relatively easy to label by systemic injections of fluorescently labeled probes (Movies 1–4; Figure 3(a)). This approach has provided not only the contrast to resolve the structure of the blood vessels but also a tool to measure the blood flow locally (Helmchen and Kleinfeld, 2008). For example, in mice and rat models for stroke, alterations in the vascular flow and in the size of the capillaries were monitored in the brain cortex during ischemia and reperfusion (Masamoto *et al.*, 2012). Systemic injections of fluorescently labeled bovine serum albumin (BSA) or dextrans have been used for a variety of applications such as, to measure glomerular filtration and tubular reabsorption in the kidney both in normal and ischemic conditions (Camirand *et al.*, 2011; Kang *et al.*, 2006; Yu *et al.*, 2007; Figure 3(b)), to determine

Figure 2 Excitation of intrinsic fluorescence to image tissue architecture *in vivo*. (a) List of the most common endogenous molecules excited by nonlinear microscopy techniques. (b) Excitation of NADH in rat tissues by 2P microscopy. Tissue architecture of various rat organs (liver, kidney, brain cortex, skeletal muscle, epididymus, bladder, prostate, and lacrimal glands) was observed by 2P microscopy using 740 nm as excitation wavelength to reveal cellular and mitochondrial NADH, which provides tissue contrast. (c) Second and third harmonic signals from rat and mouse tissues. Upper panels: Collagen fibers were revealed by SHG (excitation 930 nm) in the salivary gland and heart of rats, and in the tongue of a mouse. Lower panels: THG/SHG three-dimensional reconstruction of tissue interfaces in the mouse dermis (1180 nm excitation wavelength). THG (cyan) was generated by fat cells (f), nerve fibers (n), flowing erythrocytes labeling perfused blood vessels (arrowheads, left panel), and cell bodies interspersed in loose connective tissue (arrowheads, right panels). SHG (red) was confined to collagen bundles (c) and striated muscle fibers (m) (courtesy of Peter Friedl, adapted from Weigert, R., Sramkova, M., Parente, L., Amornphimoltham, P., Masedunskas, A., 2010. Intravital microscopy: A novel tool to study cell biology in living animals. *Histochemistry and Cell Biology* 133, 481–491). (d) Comparison between conventional H&E staining and 2P microscopy – H&E staining of rat salivary glands (left panel) and 2P microscopy (excitation wavelength 740 nm) of the exposed glands *in situ* (center and right panels). Acini (dotted line and arrow) and large ducts (arrowhead) are clearly visible. Adapted from Weigelin, B., Bakker, G., Friedl, P., 2012. blood flow patterns in the vasculature bed of pancreatic islets (Nyman *et al.*, 2008), to measure the vascular flow in the olfactory bulb (Chaigneau *et al.*, 2003; Zhang and Murphy,

2007), to study angiogenesis during wound healing (Holstein *et al.*, 2011), to unravel the signaling components mediating vasculature leakage (Gavard *et al.*, 2009; Figure 3(b)), and

Figure 3 Imaging tissue architecture and tissue response in live animals. (a) Diagram of systemic injections of fluorescent dyes in the rodent tail vein, and set up for IVM. (b) Dynamics of the vasculature in kidney, salivary glands, and skin revealed by systemic injections of fluorescent dextran. Fluorescently labeled dextran (red) were injected in the tail vein of anesthetized rats and the appearance in the vasculature was imaged by 2P microscopy. In the kidney (left panels) the proximal tubules (PT) and the distal (DT) tubules were revealed by endogenous fluorescence (green, excitation 740 nm). Dextran appears first in the microvasculature (arrows), then in the PT (arrowheads), and finally in the DT (asterisks) (Movie 1). In the salivary glands (center panels) the nuclei were revealed by injections of the nuclear dye Hoechst (blue) (Movie 2). In the skin (right panels), interleukin 8 (IL8) was injected locally to induce vasculature leakage, as shown by the diffusion of the dextran into the tissue (Movie 3). (c) CFDA was injected systemically and uptaken by the hepatocytes in the liver. After its processing and release into the bile canaliculi CFDA becomes fluorescent (green) and labels the bile canaliculi (arrowheads) providing a tool to analyze bile flux (Movie 4). (d) Change in morphology of the blood vessels in tumors *in situ*. The vasculature of an immunocompromised mouse was highlighted by the systemic injection of dextran (green) before (left panel) and after (center and right panel) the implant of breast cancer cells in the back (red). Note the change in shape and tortuosity of the blood vessels. Images were acquired by 2P microscopy (excitation wavelength 930 nm). Adapted from Gavard, J., Hou, X., Qu, Y., *et al.*, 2009. Figure 4 Approaches to perform long-term imaging in the brain – (a) Imaging the brain requires the surgical removal or the thinning of a small area of the skull. With the thinned skull chronic imaging is achieved by using a microscope lens (b). After removal of the skull and once the cortex is exposed several approaches can be used to image the area of interest such as, direct imaging, installation of a permanent cranial window (c), and the insertion of gradient Index (GRIN) lenses (d) or microprisms (e). Recently, permanently implanted optical guides have enabled imaging deep regions of the brain for periods up to 1 year (f).

recently to investigate the microvasculature in the lung (Presson *et al.*, 2011), and in the heart (Lee *et al.*, 2012; Vinegoni *et al.*, 2012).

Furthermore, the combination of dextran injections with procedures to perform long-term IVM has been instrumental in cancer biology to study tumor-mediated angiogenesis. In various murine tumor models, studies based on detailed three-dimensional analysis of the vascular morphology have clearly shown the dramatic changes in the structure and function of the blood vessels including their aberrant branching and increased permeability (Fukumura *et al.*, 2010; Smith *et al.*, 2008; Tozer *et al.*, 2005; Vakoc *et al.*, 2009; Figure 3(d)).

Specific tissue components can also be labeled by the selective delivery of small molecules to the organ of interest. For example, dextrans have been injected into the salivary duct of

live rats and mice to highlight the apical pole of the glandular epithelium and to visualize G protein-coupled receptor-stimulated fluid secretion (Masedunskas *et al.*, 2011a,b; Sramkova *et al.*, 2009). Other dyes, such as sodium fluorescein, carboxyfluorescein (CFDA) or Rhodamine 123, have been injected in live rats to visualize and to measure the dynamics of hepatic transport into the bile canaliculi (Babbey *et al.*, 2012; Liu *et al.*, 2012; Figure 3(c)). Curcumin and methoxy-04 have been used to label and monitor amyloid plaques in a mouse model for Alzheimer's disease (Garcia-Alloza *et al.*, 2007; Spires *et al.*, 2005). In addition, metabolic processes have been imaged *in vivo*, as well. For example, tissue energetics has been measured during ischemia and reperfusion in liver transplant using specific dyes such as, TMRM and Rhodamine 123, that detect changes in the mitochondrial

membrane potential (Theruvath *et al.*, 2008; Zhong *et al.*, 2008), or by measuring oxygen consumption using Ru (phen₃)²⁺ (Paxian *et al.*, 2004).

Imaging the Behavior of Individual Cells *In Vivo*

Imaging individual cells in live animals has revolutionized several fields such as neurobiology, immunology, cancer biology, and stem cell research (Table 2).

The neurosciences, in particular, have been the first discipline developing long-term *in vivo* imaging thanks to the establishment of surgical procedures to expose the brain cortex, and the implantation of chronic port of observations such as, cranial windows, imaging guide tubes for micro-optical probes, or micropiprims (Figure 4; Barretto *et al.*, 2011; Chia and Levene, 2009; Levene *et al.*, 2004; Svoboda and Yasuda, 2006; Xu *et al.*, 2007). Moreover, this field has tremendously benefited from the development of several transgenic mouse models expressing fluorescent reporters in specific neuronal populations (Barretto *et al.*, 2011; Chia and Levene, 2009; Levene *et al.*, 2004; Svoboda and Yasuda, 2006; Xu *et al.*, 2007). In particular, the so called 'brainbow' mouse, that is based on the random expression of various combinations of fluorescent variants of the green fluorescent protein (GFP), has opened the door to investigating neuronal interconnections *in vivo* (Livet *et al.*, 2007; Loulier *et al.*, 2014). This extensive toolbox has been used to investigate changes in neuronal morphology and function both during normal and pathological conditions such as, stroke (Zhang and Murphy, 2007), tumors (Barretto *et al.*, 2011), neurodegenerative diseases (Merlini *et al.*, 2012), and infections (McGavern and Kang, 2011).

In cancer biology, IVM has been instrumental in understanding the mechanisms of tumor progressions and the modality of invasion and metastasis of cancer cells within the tumor microenvironment (Beerling *et al.*, 2011). This has led to the discovery of novel mechanisms that were not appreciated in *in vitro* systems. For example, in mammary tumors, the intravasation of metastatic cells has been shown to require macrophages (Wang *et al.*, 2007; Wyckoff *et al.*, 2006, 2007). In highly invasive melanomas, the migratory ability of cells has been correlated with their differentiation state, as

determined by the expression of a reporter for melanin expression (Pinner *et al.*, 2009). In a recent study, melanoma cells have been shown to migrate using a combination of different modalities (single cell and collective migration) using various preformed tracks such as myelin and collagen fibers (Weigelin *et al.*, 2012). Also in this field, the ability to extend the length of the observations from a few hours to several days have provided a plethora of novel information about the relationship between metastatic behavior and the local micro-environment, particularly the vasculature and the lymphatic system. For example, squamous cell carcinomas in the oral cavity are an ideal system to perform chronic studies on invasion since they are accessible without the need for surgical procedures (Amornphimoltham *et al.*, 2013; Patel *et al.*, 2011; Movies 5 and 6; Figures 5(a–d)). On the other hand, for other less accessible tumors various optical windows installed in selected areas of the body such as, the back (Alexander *et al.*, 2008), the mammary glands (Kedrin *et al.*, 2008), and the liver (Ritsma *et al.*, 2012b, 2013) have been successfully established (Figures 5(e) and 5(f)).

The immune response is based on a complex array of very dynamic and specialized cells, which are quickly deployed to their site of action and often exhibit very complex behaviors. IVM has been a tremendous aid in unraveling novel qualitative and quantitative aspects of cellular immunity (Movies 7–9; Figures 6(a) and 6(b); Cahalan and Parker, 2008; Germain *et al.*, 2005; Nitschke *et al.*, 2008). For example, transferring specific fluorescently labeled populations of immune cells into recipient animals has allowed the investigation of the dynamics and interactions of B lymphocytes and T cells in lymphoid tissues (Qi *et al.*, 2006), to study T cells activation (Hickman *et al.*, 2008), migration of dendritic cells (Nitschke *et al.*, 2012), and in addition, to investigate the dynamics of the immune system outside lymphoid tissues such as, in the brain during pathogen infections (Nayak *et al.*, 2012), in the heart during inflammation (Li *et al.*, 2012), and in solid tumors (Deguine *et al.*, 2010). Moreover, IVM microscopy has been instrumental to study the biology of pathogen infection (Hickman *et al.*, 2009). In the last decade, early and late stages of the infective process have been characterized *in vivo* by using various approaches and focusing on different pathogens such as *Staphylococcus aureus* and *Borrelia burgdorferi*

Figure 5 Tumor progression and invasive behavior in live animals – (a–d) Intravital imaging of tumor progression in the mice tongue injected with fluorescently labeled metastatic head and neck cancer cell lines. (a) Schematic drawings of the tongue holding device, animal set up for intravital imaging, and primary tumor mass growing in the tongue, as described in Amornphimoltham *et al.*, 2013. (b) Short-term dynamics of tumor cells. The edge of the tumor was imaged by 2P microscopy for 2 h at 5 min intervals. Individual cells were observed leaving the tumor mass (insets, red arrowheads) (Movie 5). (c) Long-term dynamics of tumor cells. The tumor was imaged on a daily basis by using 2P microscopy to reveal collagen fibers (red) and the tumor mass (green). Z-stacks were acquired at day 7 (D7), 8 (D8), and 9 (D9) and three-dimensional reconstructions (right panels, yz view) and maximal projections of the xy view (center and left panels) are shown. The extracellular matrix at the surface of the tongue was used as a reference point (center panels, arrows). Individual tumor cells were observed migrating from the tumor mass (arrowheads). (d) Tumor cells inside lymphatic vessels. Dextran was injected in the tongue in order to map the lymphatic vessels, and Z-scans were performed. Maximal projections show tumor cells (green) either in proximity (upper panel, Movie 6) or inside lymphatic vessels (lower panel). Collagen fibers in cyan. (e) Diagram illustrating some of the optical windows used for long-term imaging of tumors. Right panel shows a lymph node invaded by metastatic cells (green) and visualized via a cervical chamber. The edge of the lymph node is revealed by highlighting stromal cells (red) and collagen fibers (cyan). (f) Dorsal skin chamber to image tumor progression and tumor-mediated angiogenesis (left panels). Colon cancer cells (red) were inoculated and after 7 days the overall view of tumor mass and blood vessels (green) observed at a low magnification using a combination of transmitted light and confocal microscope (center panel). Change in the morphology of the blood vessels from day1 to day10 (D1–D10) after tumor injection. Note the formation of new vessels and the branching out from an existing one (arrows). Adapted from Amornphimoltham, P., Rechache, K., Thompson, J., *et al.*, 2013. Rab25 regulates invasion and metastasis in head and neck cancer. Clinical Cancer Research: An Official Journal of the American Association for Cancer Research 19, 1375–1388.

Figure 6 Imaging individual cells in live animals – (a–b) Dynamics of immune cells. (a) A wound was generated in the skin of a transgenic mouse expressing the actin reporter lifeact. After 1 day (D1), the dynamics of the immune cells recruited to the wound site was imaged by 2P microscopy (Movie 7). (b) A granulocyte moving inside a blood vessel in the mammary gland of a mouse expressing GFP-tagged myosin IIb (green) and labeled with mitotracker (red) was imaged in time-lapse mode by using confocal microscopy (Movie 8). (c) Dynamics of hematopoietic stem cells isolated from a transgenic mouse expressing the mTomato membrane marker (Masedunskas *et al.*, 2011a) and injected systemically in a recipient mouse. After 1 day the calvarial bone was exposed and the dynamics of the stem cells close to a large blood vessel (highlighted by injection of fluorescent dextran, green) were imaged by 2P microscopy. One of the stem cell surfs along the blood vessel and finally intravasates (Movie 9).

(Laschke *et al.*, 2005; Norman *et al.*, 2008) or *Leishmania major* (Filipe-Santos *et al.*, 2009). More recently, the advancement of the GFP technology has facilitated the generation of genetically engineered pathogens, thus increasing the number of tools to study infectious disease under physiological conditions. Two noticeable examples are in the kidney where the proliferation of a GFP-expressing uropathogenic *Escherichia coli* was studied in detail (Mansson *et al.*, 2007) and the role of resident macrophages in influencing the survival of *Candida albicans* was described for the first time (Lionakis *et al.*, 2013).

Finally, a few experimental approaches have been recently developed to track individual stem cells and to study their behavior in living mice (Figure 6(c)). A model for long-term imaging has been established in the calvarium bone marrow to examine the relationship between hematopoietic stem cells and blood vessel (Lo Celso *et al.*, 2009). Moreover, by using novel transgenic mice expressing specific reporters new paradigms have been recently established on stem cell maintenance either in the skin (Rompolas *et al.*, 2012, 2013) or in the intestinal crypts (Ritsma *et al.*, 2014).

Imaging Subcellular Structures *In Vivo*

The main challenge in performing subcellular imaging in live animals is the minimization of the motion artifacts derived from the heartbeat and the respiration, while maintaining the integrity and the physiology of the tissue. Indeed, small shifts along the three axis make practically impossible to visualize structures whose sizes are in the micron or submicron range, whereas it marginally affects larger structures. Recently, this issue has been overcome by using a combination of strategies, which include: (1) the development of surgical procedures to

expose and to proper position the organ of interest (Masedunskas *et al.*, 2013), (2) the use of specific organ holders (Cao *et al.*, 2012; Masedunskas *et al.*, 2012a), (3) the synchronization of the imaging acquisition with the heartbeat and respiration (Li *et al.*, 2012; Presson *et al.*, 2011), and (4) novel software to correct for image distortion (Dunn *et al.*, 2014).

Nuclei have been easily imaged, thus making possible to study processes, such as cell division and apoptosis. For example, mitosis and the structure of the mitotic spindle were followed in a xenograft model of human cancer upon treatment with the anticancer drug Paclitaxel, revealing significant differences between *in vitro* and *in vivo* models (Orth *et al.*, 2011); cell division was followed in the hair-follicle stem cells of transgenic mice thus determining that epithelial–mesenchymal interactions are essential for stem cell activation and regeneration (Rompolas *et al.*, 2012); finally, apoptosis has been studied in the liver of live mice injected with the FAS ligand Jo2 by using confocal microendoscopy (Goetz *et al.*, 2011).

Another field where subcellular IVM has been utilized is membrane trafficking (Table 3). The first trafficking event successfully imaged *in vivo* is the endocytosis of various markers, such as fluorescently labeled dextrans, folate, or the aminoglycoside gentamicin, in the kidney proximal tubuli (Movies 10–12; Figure 7; Dunn *et al.*, 2002; Sandoval *et al.*, 2004). However, in these pioneering studies the residual motion artifacts limited the imaging to short periods of time. A major breakthrough was accomplished in rodents' salivary glands where various probes (dextrans, BSA, and transferrin) were observed to rapidly internalize in the stromal cells surrounding the salivary gland epithelium in an actin cytoskeleton-dependent fashion and traffic throughout the endo-lysosomal system (Masedunskas *et al.*, 2012b;

Figure 7 IVM of subcellular organelles (Endocytosis). (a) Set up for studying endocytosis *in vivo* in salivary glands. Fluorescently labeled molecules are injected into the tail vein. The probes reach the salivary glands, are released into the tissue through the fenestrated capillaries, and get internalized into the stromal cells. (b) Time-lapse imaging of dextran internalization in live animals – A rat was injected with Hoechst 33342, and followed by dextran injection into the tail artery, which highlights the vasculature almost instantly. A few minutes after the injection, small endocytic vesicles appeared inside cells adjacent to a blood vessel, which increased over time both in number and in size (Movie 10). (c) Dynamics of early endosomal fusion. Small endocytic vesicles (green) fuse to each other to form larger structures (arrowheads). Lysosomes are highlighted in red (arrowheads) (Movie 11). (d) Endocytosis of a systemically injected dextran into the kidney of a transgenic mouse expressing the membrane marker m-GFP. The dextran (red) is transported from the microvasculature into the proximal tubules, and then internalized in small endocytic vesicles (arrows) (Movie 12).

Masedunskas and Weigert, 2008; Figure 7). Interestingly, these studies revealed significant differences in the kinetics of internalization of transferrin and dextran when compared to cell cultures, indicating that the environment *in vivo* plays a major role in the regulation of membrane trafficking (Masedunskas et al., 2012b; Weigert, 2014). Endocytosis has also been studied in cancer models. For example, in head and neck cancer xenografts the uptake of a fluorescent epidermal growth factor (EGF) conjugated to carbon nanotubes has been characterized underscoring a potential role for this pathway as a therapeutic target (Bhirde et al., 2009). Moreover, the recycling of membranes controlled by the small GTPase Rab25 has been

shown to regulate the ability of tumor cells to invade and metastasize to cervical lymph nodes *in vivo* (Amornphimoltham et al., 2013).

The ability to almost completely minimize the motion artifacts has enabled performing rigorous quantitative analysis of membrane trafficking processes, such as regulated exocytosis (Masedunskas et al., 2011a). Indeed, in salivary glands, the use of transgenic mice expressing selected fluorescently tagged probes has revealed that the regulation and the modality of exocytosis differ between *in vivo* and *in vitro* systems (Movies 13 and 14; Figures 8(a–c)). In addition, it is important to emphasize that the ability to perform transient

Figure 8 IVM of subcellular organelles (Exocytosis). (a) Diagram of the experimental set up to image regulated exocytosis in the salivary glands of transgenic mice expressing cytoplasmic GFP (green) that is excluded from the secretory granules (arrowheads) and it is enriched at the apical plasma membrane where exocytosis occurs (arrow). Note that the apical plasma membrane is enriched in GFP and actin as revealed by counter-staining with phalloidin (red) (Insets). (b) Time series of a single granule (white arrows) fusing with the APM (red line). A continuity between the lumen of the granule and the acinar canaliculus is visible (red arrowhead, [Movie 13](#)). (c) Comparison between regulated exocytosis *in vivo* and *ex vivo* in salivary glands. *In vivo*, regulated exocytosis is stimulated by β -adrenergic stimulation and involves the integration of the granular membrane into the apical plasma membrane (gradual collapse). In *ex vivo* preparations regulated exocytosis is elicited by either the β -adrenergic or the muscarinic receptors which trigger compound exocytosis. (d) Diagram of the cannulation of the salivary duct to deliver fluorescent molecules and plasmid DNA to perform transient *in vivo* transfections. (e) Single acinar cells showing GFP-lifect enriched at the apical plasma membrane in resting conditions (left panel, arrowhead) and recruited onto the secretory granules upon stimulation (right panel, arrow). (f) Time-lapse sequence of the recruitment of GFP-lifect onto the secretory granules (arrows) ([Movie 14](#)). Diagram illustrating the recruitment of F-actin and Myosin II onto the secretory granules. Adapted from Masedunskas, A., Sramkova, M., Parente, L., *et al.*, 2011a. Role for the actomyosin complex in regulated exocytosis revealed by intravital microscopy. *Proceedings of the National Academy of Sciences of the United States of America* 108, 13552–13557.

transfections *in vivo* (Sramkova *et al.*, 2009; Figure 8(d)) combined with a pharmacological approach has enabled the identification of specific components regulating this process. Specifically, these studies revealed the requirement for the assembly onto the secretory granules of a complex formed by F-actin and two isoforms of the motor protein myosin II, which are required to facilitate the completion of the exocytic process (Figures 8(e) and 8(f); Masedunskas *et al.*, 2011a,b, 2012c,d). These results underscore that the dynamics of the assembly of the actin cytoskeleton can be studied both qualitatively and quantitatively in live animals. In addition, this approach has shown that some of the mechanisms that contribute to regulate the apical plasma membrane homeostasis *in vivo* cannot be recapitulated in *in vitro* model systems (Masedunskas *et al.*, 2011b, 2012c). Similar approaches have begun to be used to investigate other models for protein secretion, such as the exocytosis of vesicles transporter type 4 (Glut4) and its insulin-dependent translocation to the plasma membrane (Lauritzen *et al.*, 2008, 2010). This represents a very powerful experimental model that bridges physiology and cell biology and has the potential to provide fundamental information on metabolic diseases.

The use of IVM to image intracellular organelles is rapidly expanding to other areas of cell biology. For example, the development of a mouse expressing the autophagic marker LC3-GFP has enabled imaging the dynamics of autophagy upon starvation in several organs such as liver, pancreas, and skeletal muscle (Cao *et al.*, 2012). This model system has been instrumental to reveal that lipid droplets in the liver contribute to the initiation of starvation-induced autophagy (Dupont *et al.*, 2014). Moreover, the dynamics of lipid droplets have been studied in the liver by using THG without the need for exogenous labeling (Debarre *et al.*, 2006) and the dynamics of mitochondria have been imaged in the salivary glands and in the liver by using various fluorescent probes (Masedunskas *et al.*, 2012a; Sun *et al.*, 2005; Weigert *et al.*, 2010). Finally, recent studies addressed the imaging of intracellular signaling in live animals using a variety of FRET-based probes specifically designed to measure the levels of intracellular calcium, or cAMP and the activity of proteins such as calpain (Ritsma *et al.*, 2012a; Rudolf *et al.*, 2006; Stockholm *et al.*, 2005).

Concluding Remarks

IVM is a powerful technique that has already begun to provide major contributions to several areas of biology and it is steadily broadening its range of application. The strength of this approach resides in the unique opportunity to study a given process in real time in the context of a fully developed tissue. Although *in vitro* and *ex vivo* model systems are still the most widely used tools to study biological processes at a molecular level, they are often inadequate to reconstitute the complexity of the signaling, metabolic cues, and structural organization that are the key features of multicellular organisms. In this respect, IVM is the obligatory choice to investigate tissue physiopathology, and the development of subcellular IVM has created new avenues to link tissue function to cellular and subcellular processes.

We foresee that the continuous development of novel tools specifically tailored to IVM, such as optics, imaging software, surgical procedures, fluorescent probes, and transgenic animal models will rapidly make IVM a 'standard' tool for studying biology.

Glossary

Channelrhodopsin (ChR) ChR is a light-gated ion channel from algae, which contains a retinal cofactor and is opened by light, that is the channel becomes permeable upon illumination.

Excitability The ability of a cell to react to a stimulus with changes in membrane potential, for example, to generate an action potential.

Glutamate receptors (GluRs) GluRs are synaptic signaling proteins, which sense glutamate, an excitatory neurotransmitter that is released from the presynaptic terminal. Two classes exist: Ionotropic glutamate receptors (iGluRs), which are tetrameric ion channels that open upon glutamate binding and allow the flux of ions, and metabotropic glutamate receptors (mGluRs), which are

dimeric G protein-coupled receptors (GPCRs) that cause G protein activation.

Light-sensitive proteins Proteins which typically contain a light-absorbing cofactor that upon illumination triggers changes in protein function.

Optogenetics Experimental strategies that combine the advantages of optical manipulation with the abilities of genetic targeting.

Photoswitch A chemical compound that reversibly changes its conformation or chemical properties upon illumination with light.

Photoswitchable tethered ligand (PTL) A ligand that encompasses a photoswitch to light-control its binding and unbinding behavior, as well as a group for covalent tethering to the protein of interest.

Light As a Tool in Biology

Light is orthogonal to most biological systems and therefore fairly noninvasive. Moreover, light provides the resolution to resolve most biological processes in space and time. Not surprisingly, this made light microscopy a pivotal tool in biological research. But in the past decade, light has also become an increasingly valuable tool in another way. Next to the purpose of visualization in imaging-based approaches, the advantages of light are now also utilized to manipulate biological processes. Through the use of light-sensitive proteins and chemical photoswitches it has become possible to optically control numerous functions in living cells, which in combination with modern genetics has enabled a new, versatile method for biological experimentation, called optogenetics.

Optogenetics – Manipulating Molecules, Cells, and Organisms with Light

Optogenetic approaches allow for the optical control of a desired molecular or cellular function through targeting of light-sensitive (bio)molecules to a subset of genetically defined cells. The motivation for using such optogenetic strategies is twofold: (1) Light offers high spatial and temporal resolution for manipulating biological processes in living cells and organisms, with a precision and selectivity that is hard to achieve by other means. (2) Genetic tools enable the experimenter to define precisely, which cells are manipulated. Optogenetics thus gives a handle to probe in real time how specific molecules or cells contribute to complex cellular networks, to the function of organs or the behavior of whole organisms. Due to these advantages, optogenetic approaches

are now applied in many experimental paradigms (Miesenböck, 2009, 2011; Fenno *et al.*, 2011). As we will describe in the following sections, the key factors for optogenetic experimentation are the light-sensitive (bio)molecule used, the method of genetic targeting, and the means of illumination (Figure 1).

Light-Sensitive (Bio)molecules

Modulation with light can be achieved either through the expression of light-sensitive proteins or through the application of synthetic photoswitches that target specific proteins or biological processes. Examples of various optogenetic tools along with their key properties are given in Table 1. This list represents only a small selection of the available tools, also because the development of optogenetic methods continues to be an active area of research.

Naturally occurring light-sensitive proteins contain cofactors, which absorb light in certain wavelength ranges, and, which upon illumination modulate protein function. For instance, vision in vertebrates and invertebrates is mediated by rhodopsins ('visual pigments'), which are G protein-coupled photoreceptors that contain a covalently bound retinal cofactor. In the case of rhodopsins, the absorption of light induces an isomerization of the 11-*cis* form of retinal to an all-*trans* form, which leads to receptor activation and subsequent activation of G proteins and downstream signaling cascades (Palczewski, 2006). Indeed, invertebrate rhodopsins, which couple to the G_q class of G proteins and thereby indirectly increase cellular excitability, were used in the first optogenetic experiment (Zemelman *et al.*, 2002). However, invertebrate rhodopsins have found limited application, since their use in vertebrates requires the expression of additional G_q signaling components. On the other hand, an increasing number of

Figure 1 Scheme of optogenetic experimentation. (a) Light-sensitive or modified proteins (green box), which change their function in response to light, are used as tools to optically control specific cellular functions. (b) These light-sensitive proteins are expressed in defined regions or subsets of cells using genetic tools, such as viruses, driver lines, or transgenic animals. This can provide high specificity to which cells are manipulated, for example, which neurons in a certain brain region are targeted. (c) Illumination with light is used to control the desired molecular or cellular function, if necessary, with high spatial and/or temporal resolution. The observed read-out of an optogenetic experiment depends on the system and can be virtually anything, from changes in molecular processes, over cellular network functions to changes in animal behavior.

Table 1 Examples of light-sensitive proteins and chemical photoswitches used for optogenetic studies

Optogenetic tools	Function	Used for	References
<i>Rhodopsins (retinal cofactors)</i>			
Vertebrate rhodopsin	Light-activated G protein-coupled receptor (GPCR)	G _{i/o} signaling	Li <i>et al.</i> (2005); Masseck <i>et al.</i> (2011)
Channelrhodopsin (ChR)	Light-gated ion channel	Depolarization	Boyden <i>et al.</i> (2005)
Halorhodopsin (HR)	Light-driven Cl [−] pump	Hyperpolarization	Zhang <i>et al.</i> (2007)
Archaeorhodopsin (Arch)	Light-driven H ⁺ pump	Hyperpolarization	Chow <i>et al.</i> (2010)

Adenylyl cyclases (PACs)	Light-driven cAMP production	cAMP signaling	Schröder-Lang <i>et al.</i> (2007); Raffelberg <i>et al.</i> (2013)
Isolated LOV/BLUF domains	Conformational changes	Engineering	Möglich and Moffat (2010)
<i>Phytochromes (bilin cofactors)</i>			
PhyB-PIF3	Light-controlled protein association	Dimerization, co-localization	Shimizu-Sato <i>et al.</i> (2002); Möglich and Moffat (2010)
<i>Synthetic photoswitches (azobenzenes)</i>			
Photoswitchable tethered ligands (PTLs)	Activation/inhibition of ligand-gated receptors	iGluRs mGluRs AChRs GABA _A Rs	Volgraf <i>et al.</i> (2006); Reiner <i>et al.</i> (2015) Levitz <i>et al.</i> (2013) Tochitsky <i>et al.</i> (2012) Lin <i>et al.</i> (2014)
Photoswitchable tethered blockers	Pore block of K ⁺ channels	K _v , SK, K _{2P}	Banghart <i>et al.</i> (2004); Sandoz <i>et al.</i> (2012)
Photoswitchable allosteric modulators	Allosteric modulation	P2X receptors	Lemoine <i>et al.</i> (2013); Browne <i>et al.</i> (2014)

vertebrate rhodopsin variants are utilized in optogenetic experiments. For instance, rat rhodopsin 4 (RO4), which is G_{i/o} coupled, can be used for light-induced hyperpolarization of cells through the activation of GIRK channels, while it also inhibits presynaptic Ca²⁺ channels (Li *et al.*, 2005). Importantly, the specificity of rhodopsin-mediated signaling can be increased by targeting the rhodopsins to specific cellular localizations by fusing C-termini from other G protein-coupled receptor (GPCR) to tap into local G protein signaling cascades (Oh *et al.*, 2010), or by replacing the intracellular loops to achieve coupling to G_s or G_q pathways (Kim *et al.*, 2005; Airan *et al.*, 2009). Recently, also melanopsin and cone opsins, the latter providing very high light sensitivity, have

been exploited as optogenetic tools (Masseck *et al.*, 2014; Spoida *et al.*, 2014).

Another, very versatile class of light-sensitive proteins is given by microbial rhodopsins, which like animal rhodopsins contain a retinal cofactor, but comprise other functionalities than G protein activation. Channelrhodopsins (ChRs), for instance, are light-gated ion channels controlling phototaxis in green algae (Nagel *et al.*, 2002, 2003), whereas halorhodopsins (HRs) and archaeorhodopsins (Archs), which are both of archaeal origin, are light-driven chloride and proton pumps, respectively. Photo-activation of ChRs or HRs/Archs directly affects the ionic distribution across the cell membrane, which allows for the rapid control of membrane potential and

excitability. We discuss this application in more detail in the section Light-Sensitive Proteins To Control Cellular Excitability (Boyden *et al.*, 2005; Li *et al.*, 2005; Han and Boyden, 2007; Zhang *et al.*, 2007; Chow *et al.*, 2010). Typically, microbial rhodopsins are further optimized by protein engineering, i.e., by amino acid substitutions or the generation of chimeric proteins, to improve their expression in the desired eukaryotic hosts and to achieve sensitive and/or fast activation with light of different wavelengths (Lin *et al.*, 2009; Gunaydin *et al.*, 2010; Berndt *et al.*, 2011; Mattis *et al.*, 2012; Lin *et al.*, 2013; Klapoetke *et al.*, 2014). Recently, also synthetic retinal analogs were explored for tuning the spectral and temporal characteristics of rhodopsin-based tools (AzimiHashemi *et al.*, 2014).

Bacteria and plants are also a rich source of photoreceptors with cofactors other than retinal, including xanthopsins, phytochromes, cryptochromes, and LOV and BLUF domain-containing photoreceptors (Table 1; Möglich *et al.*, 2010). Several naturally occurring photoreceptors are used as optogenetic tools, such as photo-activated adenylyl cyclases (PACs) that can be used to directly control cellular cAMP levels. PACs have been found in the flagellate *Euglena gracilis* and in bacteria and are either controlled by flavin-containing BLUF or LOV photoreceptor domains (Schröder-Lang *et al.*, 2007; Stierl *et al.*, 2011; Raffelberg *et al.*, 2013). The modular nature of plant photoreceptor also facilitates the engineering of new light-sensitive functionalities by combining different photoreceptor 'receiver' domains with different effector 'output' domains (Möglich and Moffat, 2010; Pathak *et al.*, 2013). A popular choice are LOV domains, in which illumination leads to the dissociation and unfolding of a C-terminal helix (Harper *et al.*, 2003). LOV domains have therefore been used as conformational switches to control other proteins, for example, DNA-binding proteins (Strickland *et al.*, 2008), enzymatic activities (Lee *et al.*, 2008), or signaling proteins such as small GTPases (Wu *et al.*, 2009) or receptor tyrosine kinases (Grusch *et al.*, 2014). Cryptochromes and plant phytochromes, which undergo blue- and red-light induced dimerization, respectively, are popular tools to control protein association and co-localization (Shimizu-Sato *et al.*, 2002; Kennedy *et al.*, 2010). Recently a bacterial phytochrome was used to construct a red-light-activated cAMP/cGMP-specific phosphodiesterase (Gasser *et al.*, 2014).

Another strategy to obtain light-control is to rely on chemical photoswitches to manipulate proteins that are not light-sensitive otherwise. A wide variety of photoswitches exists (Szymanski *et al.*, 2013), with azobenzene derivatives being the most popular choice to control biomolecules (Beharry and Woolley, 2011). Azobenzenes, which undergo a photo-induced *cis/trans* isomerisation, have excellent photostability and can be used to build photoswitchable ligands, blockers, or allosteric modulators (Table 1). In the case of these optochemical approaches the genetic specificity is ensured by the target molecule – typically a protein that carries a single amino acid mutation to covalently bind the photoswitch. We give a more detailed description of this approach in the section Optochemical Approaches To Control Specific Receptors and Ion Channels.

The example sections below provide more detailed descriptions of how light-sensitive proteins, as well as chemical photoswitches are used as optogenetic tools. When choosing a

tool for experiments, it is necessary to pay close attention to its characteristics, including the expression in the desired host system, the necessity to add cofactors, possible unspecific effects, dark activity, wavelength sensitivity, and so on. In all cases, it is mandatory to perform proper control experiments in the context of the system under investigation, in particular to establish that no unspecific effects arise from just expressing the optical actuator or from just applying light.

Genetic Targeting

While optical control on its own is powerful, the full strength of optogenetic approaches typically comes from the ability to limit the manipulation to certain types or subsets of cells (Zemelman and Miesenböck, 2001). Here optogenetics benefits from the numerous genetic tools that have been developed to drive expression of reporter proteins in specific cell types. These tools encompass gene delivery methods (e.g., biolistic, chemical, and viral transfection or chromosomal integration), as well as cell-type specific promoters and driver lines (e.g., GAL4/UAS or Cre-Lox systems) that have been identified or generated for various model organisms, such as worm, fly, fish and mouse. Applications in living rodents and primates often rely on a spatially restricted viral delivery using lenti- or adeno-associated viral (AAV) vectors in combination with specific promoters or enhancers. Moreover, a number of transgenic mice expressing rhodopsins directly or in a recombinase-dependent fashion have been developed (Arenkiel *et al.*, 2007; Fenno *et al.*, 2011; Madisen *et al.*, 2012). These genetic tools are extremely powerful, since they can be combined to achieve conditional labeling patterns, to get additional pharmacological control on developmental timescales, or to achieve retrograde labeling of neurons. New genome editing tools and new transgenic animals are likely to enhance these capabilities further.

Delivery of Light

The third factor in optogenetic experimentation is the delivery of an adequate light stimulus. Again numerous options exist, depending on the particular application. Lasers, diode lasers, and now more often inexpensive light emitting diodes (LEDs) are used to generate light of appropriate wavelengths and intensity. In cases, where high spatial resolution is paramount, for example to limit the manipulation to single cells or sub-cellular regions, a combination with an objective, typically a microscope, is used to deliver a small or patterned light stimulus. Laser scanning of large areas is possible, although this may decrease the sensitivity of optogenetic tools that are transiently activated. Alternative options are micromirror devices or holographic methods. Furthermore, to achieve high resolution in all dimensions, for example, in multi-layered tissues, it might be necessary to rely on two-photon methods (Papagiakoumou *et al.*, 2010; Vaziri and Emiliani, 2012).

In other cases spatial resolution is not a major concern, or, it is even desirable to manipulate cells in a wide region, for example, across some hundred microns in a layer of the cerebral cortex. In such cases, illumination of deeper regions can be provided through an implanted optical fiber, or, of more accessible areas through an implanted window.

Red-light activated photoreceptors can be advantageous, since red light penetrates deeper into tissue and in this way even transcranial activation has been achieved in mice (Lin *et al.*, 2013). In the case of smaller and transparent animals like fly, worm or zebrafish larvae light can be applied from the outside, either as full-field flash or again as a patterned light stimulus to activate individual cells.

Light-Sensitive Proteins to Control Cellular Excitability

An early example is the use of optogenetic tools to control the membrane potential and thereby neuronal excitability (Zemelman *et al.*, 2002; Banghart *et al.*, 2004). An important

breakthrough was the cloning and characterization of channelrhodopsin-2 (ChR2), a light-gated ion channel from the green algae *Chlamydomonas reinhardtii* that becomes conductive under illumination with blue light (Nagel *et al.*, 2003; Table 1). Importantly, ChR2 can be robustly expressed in mammalian cells, including neurons, and light-induced channel opening leads to a significant depolarization of the cell membrane thereby increasing neuronal excitability. Indeed, light can be used to induce action potential firing with high precision (Figures 2(a)–2(c); Boyden *et al.*, 2005; Li *et al.*, 2005). In most systems ChR2 works sufficiently well with endogenous levels of retinal so that no exogenous retinal has to be supplemented. The utility of ChR2 for activating neurons was quickly realized in different systems – next to cultured neurons it was used in the spinal cord and in chicken embryos (Li *et al.*, 2005), soon after in hippocampal slice

Figure 2 Optical control of neuronal excitability with ChR and HR. (a) ChR is a blue light-activated ion channel that, when expressed in mammalian cells, leads to a light-induced decrease in membrane potential (depolarization). (b) Voltage-clamp recording of a cell expressing ChR2. Illumination (blue bar) leads to an inward current, mainly through an influx of sodium ions. (c) Optical control of action potential firing in a ChR2 expressing neuron. Brief light pulses (blue bars) elicit single action potentials in a current-clamp recording. (b and c) Adapted with permission from Boyden, E.S., Zhang, F., Bamberg, E., Nagel, G., Deisseroth, K., 2005. Millisecond-timescale, genetically targeted optical control of neural activity. *Nature Neuroscience* 8, 1263–1268, © 2005, Macmillan Publishers Ltd. (d) HR is a yellow light-driven chloride pump, which means that illumination causes an increase in membrane potential (hyperpolarization). (e) Voltage-clamp recording of a cell expressing *Natronomonas pharaonis* HR (NpHR). Light (yellow bar) drives NpHR to pump chloride ions into the cell, which results in an outward photocurrent. (f) Optical silencing of neuronal activity in a NpHR expressing neuron. Yellow light reversibly suppresses action potential firing. In this current-clamp recording firing had been induced through a current injection. (e and f) Adapted with permission from Zhang, F., Wang, L.P., Brauner, M., *et al.*, 2007. Multimodal fast optical interrogation of neural circuitry. *Nature* 446, 633–639, © 2007, Macmillan Publishers Ltd.

after stereotactic injection of ChR2-pseudovirions into mice (Ishizuka *et al.*, 2006), in the worm *Caenorhabditis elegans* to control behavior (Nagel *et al.*, 2005), and in the retina of mice models of inherited blindness to restore light sensitivity (Bi *et al.*, 2006). From this point on, ChR2 quickly became a standard tool to functionally probe connectivity, to study the role of particular subtypes of neurons or brain regions for circuit function, or to control the behavior of animals (Tye and Deisseroth, 2012; Reiner and Isacoff, 2013). Many improved variants of ChR are now available, including variants that are optimized for high frequency stimulation, more sensitive variants that turn off slowly after illumination, and variants for two-photon or red-light activation (Lin *et al.*, 2009; Gunaydin *et al.*, 2010; Berndt *et al.*, 2011; Mattis *et al.*, 2012; Lin *et al.*, 2013; Klapoetke *et al.*, 2014). Other variants have increased Ca^{2+} -permeability (Kleinlogel *et al.*, 2011), and based on recent structural and functional information (Eisenhauer *et al.*, 2012; Kato *et al.*, 2012) chloride permeable ChR variants were engineered, which can be used to shunt the membrane potential and thereby suppress excitations (Berndt *et al.*, 2014; Wietek *et al.*, 2014).

Soon after the introduction of ChR the first tools for directly hyperpolarizing cells were introduced in order to silence neurons and to prevent action potential firing. This was achieved with halorhodopsin from *Natronomonas pharaonis* (NpHR), a light-driven ion pump that upon illumination with yellow light pumps chloride ions into the cell (Figures 2(d)–2(f); Han and Boyden, 2007; Zhang *et al.*, 2007). Since ChR2 is activated by blue light and NpHR is driven by yellow light, these tools can be used in parallel to depolarize or hyperpolarize a given neuron, respectively. Somewhat later, archaeorhodopsin-3 (Arch), which is a light-driven outward proton pump from *Halorubrum sodomense*, was described as an alternative tool for silencing neurons (Chow *et al.*, 2010). Recently, a class of red-light driven cruxhalorhodopsin chloride pumps was characterized (Chuang *et al.*, 2014).

Optochemical Approaches to Control Specific Receptors and Ion Channels

The previous section gave examples of how the signaling state of cells can be controlled by the expression of light-sensitive proteins. In this section we focus on a second set of optogenetic tools that is concerned with controlling signaling proteins that are native to the cell. Such direct optical control is particularly helpful to delineate the physiological function of individual signaling components, and to test how and when these components cause changes within a given cell or within a given network. In the following example we summarize the use of photoswitchable tethered ligands (PTLs) to control ionotropic and metabotropic glutamate receptors (iGluRs and mGluRs), which are two important receptor families that sense glutamate, the major excitatory neurotransmitter in the central nervous system.

Light-Gated Glutamate Receptors – Principles

Glutamate receptors are cell surface receptors that, upon glutamate binding, generate postsynaptic currents and/or

intracellular signals. The spatio-temporal resolution of optical techniques bears great potential to understand how iGluRs and mGluRs contribute to synaptic transmission, homeostasis, and plasticity, especially since synaptic signaling happens on the timescale of few to hundreds of milliseconds and in compartments smaller than a micron in size (Reiner *et al.*, 2015). Equally desirable is a high molecular and cellular specificity of these manipulations in order to differentiate between different iGluR and mGluR family members, as well as to distinguish effects mediated by receptors located on the presynaptic neuron, the postsynaptic neuron, surrounding glia cells, or even neighboring neurons. The use of PTLs to optically control specific GluRs in real time is hence an important objective.

PTLs are ligands that are permanently linked to a specific receptor subunit and which contain an azobenzene photo-switch to control binding and unbinding of the ligand head-group to the receptor (Figures 3(a) and 3(b)). GluRs can be controlled by MAG ligands, which encompass a maleimide group for covalent attachment to an engineered cysteine residue on the receptor, an azobenzene group that serves as *cis/trans* photoswitch, and a glutamate derivative that is capable of activating the receptor (Figure 3(c)). The MAG ligand is attached to the receptor of interest by coupling to a cysteine residue, which is introduced close to the glutamate-binding site. The expression of this engineered receptor subunit is also the part that provides molecular and genetic specificity to this approach.

For instance, GluK2, a homotetrameric kainate receptor (a.k.a iGluR6), can be converted into a light-gated glutamate receptor (LiGluR) by introducing a cysteine substitution (L439C) at a position that is close to the glutamate-binding pocket, and attaching L-MAG0 to it (Figures 3(d) and 3(e)). As long as the azobenzene group is in its *trans* configuration, the glutamate headgroup of the PTL will not be able to reach into the binding pocket. Photo-isomerisation of MAG into its *cis* configuration, however, leads to rapid ligand binding and subsequent opening of the GluK2 ion channel pore (Volgraf *et al.*, 2006; Gorostiza *et al.*, 2007). A second wavelength of light can then be used to isomerize MAG back to *trans*, which reverses the effect and causes the channel to close. Photo-switching is fully reversible and azobenzenes have excellent photo-stability for hundreds of switching cycles. The efficacy and directionality of photoswitching depends on the ligand geometry (e.g., the linker lengths, which increases from MAG0 to MAG1 and MAG2) and the exact labeling position on the receptor, that is other labeling positions can result in a different outcome (Numano *et al.*, 2009).

The azobenzene photoswitch can be rationally modified, for instance, to change its wavelength sensitivity or the timescale on which the spontaneous *cis*-to-*trans* relaxation occurs: 'Regular' MAG is converted to *cis* by near UV light (~ 380 nm), and back to *trans* with blue light (~ 480 nm) (Figures 3(c)–3(e); Gorostiza *et al.*, 2007). It relaxes from *cis*-to-*trans* on the timescale of tens of minutes and thus displays bi-stable behavior on most experimental timescales. In contrast, MAG₄₆₀, which is built around a push-pull azobenzene, shows a considerably shifted action spectrum and allows for receptor activation with visible blue light (~ 460 nm) (Kienzler *et al.*, 2013). MAG₄₆₀ also has a faster *cis*-to-*trans* relaxation on the seconds timescale, i.e., the switch readily turns off in the dark. An important consequence of this behavior is, that within

Figure 3 Photoswitchable tethered ligands (PTLs) and light-gated glutamate receptors. (a) PTLs (red) are ligands that are covalently attached to a receptor of interest, for example, a ligand-gated ion channel, or, (b) a G protein-coupled receptor to control receptor activation and deactivation with light of different wavelengths. (c) MAG-PTLs for the optical control of glutamate receptors encompass a maleimide for covalent attachment to an engineered cysteine residue, an azobenzene *cis/trans* photoswitch, and a glutamate derivative for receptor activation. Regular MAGs, as shown here, are switched from *trans*-to-*cis* with near UV light (~ 380 nm) and back to *trans* with blue light (~ 500 nm) (Gorostiza *et al.*, 2007). (d) Reversible LiGluR photoswitching after expression of GluK2(L439C) and labeling with L-MAG0. The voltage-clamp recording in the presence of desensitization blocker shows bi-stable activation with 375 nm light (violet bar) and deactivation with 488 nm light (green bar) (for details see Gorostiza *et al.*, 2007). (e) LiGluR photoswitching with high time resolution. A 100 μ s light pulse leads to rapid activation and subsequent desensitization on the milliseconds timescale, which enables the real-time manipulation of these synaptic signaling proteins. (d and e) Adapted from Reiner, A., Isacoff, E.Y., 2014. Tethered ligands reveal glutamate receptor desensitization depends on subunit occupancy. *Nature Chemical Biology* 10, 273–280.

certain intensity ranges, MAG₄₆₀ can be used to sense changes in light intensity, much like a photodiode (Gaub *et al.*, 2014). Current efforts are directed toward generating MAG photoswitches for efficient two-photon activation (Izquierdo-Serra *et al.*, 2014; Carroll *et al.*, 2015), or activation with red-light (Rullo *et al.*, 2014). Modifications can be made not only to the photoswitch, but also to the protein. An extreme example is the generation of HyLighter, which instead of an unselective ion pore typical for iGluRs, contains a potassium selective ion pore and thus leads to hyperpolarization rather than depolarization (Janovjak *et al.*, 2010).

Recent experiments also demonstrate the enormous temporal resolution that can be achieved with PTLs. The azobenzene photoisomerization is an extremely rapid process and tethering the ligand generates high local concentrations, which

circumvents slow diffusion steps. At higher light intensities, light pulses as short as 10 μ s are sufficient to induce rapid binding and receptor activation, which leads to opening of GluK2 receptors in less than a millisecond (Figure 3(e); Reiner and Isacoff, 2014). This fast activation is followed by receptor desensitization on the timescale of a few milliseconds, which is typical for glutamate-induced gating of kainate receptors. Rapid optical manipulation with short light pulses thus enables biophysical studies of the gating mechanism of homo- and heteromeric iGluR complexes and can be used to precisely mimic or shape their synaptic activation profiles.

Next to iGluRs, MAG photoswitches have been applied to control mGluRs, which are G protein-coupled receptors. In the case of light-gated mGluRs ('LimGluRs') the glutamate head-group of MAG has to be linked in D-stereochemistry. Labeling

of mGluR2 at L300C (and similarly of mGluR3 at Q306C) allows for reversible photo-activation ('photo-agonism') with D-MAG0 (Levitz *et al.*, 2013). Photo-activation of these $G_{i/o}$ -coupled receptors inhibits adenylyl cyclase, activates GIRK channels and inhibits presynaptic voltage-gated Ca^{2+} channels. PTLs can also be used for photo-inhibition ('photo-antagonism'), i.e., to block receptor activation by endogenous glutamate, which is observed if mGluR2 is labeled with D-MAG1 at S302C (Levitz *et al.*, 2013). Such light-induced antagonism can be particularly useful to acutely and reversibly block the function of specific receptor subtypes circumventing the disadvantages of genetic knock-outs or pharmacological inhibition.

Light-Gated Glutamate Receptors – Applications

Apart from molecular studies, LiGluRs, and more recently LimGluRs, have been used in a variety of applications and model organisms. For instance, using LiGluR to exclusively activate postsynaptic receptors in the fly neuromuscular junction, Kauwe and Isacoff (2013) found changes in the presynaptic release probability, indicating a novel plasticity mechanism. LiGluR is also somewhat permeable to Ca^{2+} ions and has therefore been used to trigger exocytosis from neuroendocrine cells (Izquierdo-Serra *et al.*, 2013), or to evoke gliotransmission through robust Ca^{2+} influxes into astrocytes (Li *et al.*, 2012). LimGluR2, for example, has been applied to control presynaptic release probability and short-term plasticity in hippocampal neurons (Levitz *et al.*, 2013).

Next to the synaptic context, LiGluR can be used to lower the membrane potential and to control firing on short and long timescales (Szobota *et al.*, 2007; Hou *et al.*, 2011), whereas HyLighter is a hyperpolarizing tool that is well suited for neuronal silencing (Janovjak *et al.*, 2010). As optogenetic tools, LiGluR and LimGluRs have also been used on a systems-wide level. Targeted expression of LiGluR in transgenic zebrafish lines allowed dissecting the role of different types of neurons in the spinal cord for the swimming behavior of zebrafish larvae (Wyart *et al.*, 2009). LimGluR2 has been shown to affect the acoustic startle response in zebrafish (Levitz *et al.*, 2013). Like other optogenetic tools, LiGluRs and LimGluRs may also have therapeutic potential. LiGluR, in particular, has been used to restore light sensitivity to retinæ, which have lost their photoreceptor cells due to inherited forms of blindness (Caporale *et al.*, 2011; Gaub *et al.*, 2014).

Other Targets

While MAGs are designed to control glutamate receptors, the same strategy of using tethered photoswitches can be applied to other receptors and channels residing on the cell surface. So far, PTLs have been used to control acetylcholine receptors (Lester *et al.*, 1980; Tochitsky *et al.*, 2012) and GABA_A receptors (Lin *et al.*, 2014), two other important classes of neurotransmitter-gated ion channels. A similar concept has been used to control a variety of native potassium channels. In that case, a photo-switchable pore blocker is installed instead of a ligand to control access to the ion permeation pathway in a light-dependent manner (Table 1; Banghart *et al.*, 2004; Sandoz and Levitz, 2013). This strategy has been applied to voltage-gated and

calcium-regulated potassium channels (Kramer *et al.*, 2013), and it was used to provide a pharmacological signature on two-pore-domain 'leak' potassium channels (Sandoz *et al.*, 2012). A third strategy, next to using photoswitches as ligands or blockers, is to employ photoswitches at allosteric sites, where changes of the electrostatics or local conformation affects the function, as used to optically control ATP-gated P2X receptors (Lemoine *et al.*, 2013; Browne *et al.*, 2014). Overall tethered photoswitches provide a versatile strategy to control protein function with genetic precision and more compounds will become available, given the wide success of soluble photoswitches (Fehrentz *et al.*, 2011; Kramer *et al.*, 2013).

Summary – From Molecules to Systems

The manipulation with light comes as a perfect complement to our well-established techniques to visualize and monitor biological systems. Optogenetic techniques get continuously refined and are actively used in a wide range of applications. Light-sensitive molecules, such as photoreceptors or chemical photoswitches, can be turned into powerful tools, when combined with modern genetic methods and state-of-the-art optical techniques. The versatility of these approaches is enormous, since the manipulations can span from molecules, cellular compartments, and cell-to-cell communication to larger networks and complex behaviors in living animals. Moreover, optogenetics can be combined with almost any read-out, such as imaging methods, electrical recording techniques, behavioral assays, or even magnetic resonance imaging (Lee *et al.*, 2010) or ultrastructural techniques (Watanabe *et al.*, 2013). Optogenetics are also actively used in disease related research and are explored for clinical applications, for example, for vision restoration or deep-brain stimulation. These tools, although mostly pioneered with studies in the central nervous system, also hold great promise for use in other areas of biological research (Arrenberg *et al.*, 2010; Jansen *et al.*, 2015).

Introduction

Robert Hooke discovered that tissues consist of cells already in 1665. Fellow microscopists at that time, Van Leeuwenhoek and Bauer, realized that smaller structures were discernable within the cell, in particular the vacuole and the nucleus. Yet, the terminology for these cell compartments stems from the nineteenth century, when several other subcellular structures were discovered. Möbius then coined the name 'organula' – a term that was later simplified to 'organelles' – to describe these subcellular compartments. Just before the turn of the century, Camillo Golgi identified the organelle that still bears his name.

At the very beginning of the twentieth century, a student of Golgi, Emilio Veratti, found yet another subcellular structure in muscle cells, which he claimed to be distinct from the Golgi apparatus (Veratti, 1961). Veratti's work failed to convince his contemporaries, however. About 50 years later, the advent of the electron microscope finally made the unambiguous identification of Veratti's elusive organelle possible when Keith Porter and colleagues observed a network (reticulum) inside the cytoplasm of eukaryotic cells (endoplasmic). He teamed up with George Palade to obtain high-resolution images (Figure 1) and in 1954 the endoplasmic reticulum (ER)

entered the canon of cell biology as a distinct organelle separated from the cytosol by virtue of a membrane and forming a complex tubular or sheet-like network (Palade and Porter, 1954).

The Palade lab then developed a method – which still is widely used today – to obtain ER-enriched cell fractions, called microsomes (Figure 1). The physical sheering of cells causes ER vesiculation and ER-derived vesicles are then purified by differential centrifugation (Palade and Siekevitz, 1956). The combination of microscopy and biochemical assays exploiting microsomes initiated a cascade of discoveries on the function and morphology of the ER and its specialized derivative in muscle cells: the sarcoplasmic reticulum (SR). In the early 1960s, Palade and coworkers proved by pulse chase analysis using radiolabeling that the ER is the first station along the secretory pathway (Siekevitz and Palade, 1960). Günther Blobel (a pupil of Palade) and colleagues elucidated in the 1970s that client proteins enter the ER by virtue of a signal peptide (Blobel and Dobberstein, 1975).

Another milestone in ER research came when genetic screens in yeast, pioneered by Randy Schekman and colleagues (Novick *et al.*, 1980), initiated the characterization of the molecular machinery of the secretory pathway. A long list of the so-called sec proteins was identified, including several that

Figure 1 (a) One of the first sightings of the ER by electron microscopy at high resolution (n=nucleus, e=ER). Reproduced from Palade, G.E., Porter, K.R., 1954. Studies on the endoplasmic reticulum. are fundamental to ER function. Through the work of Ari Helenius and coworkers it became clear in the late 1980s/early 1990s that stringent quality control is exerted on protein folding in the ER (Hurtley *et al.*, 1989). At around the same time, pioneering work from Kazutoshi Mori and Peter Walter (a pupil of Blobel) initiated research on the unfolded protein response (UPR) (Cox *et al.*, 1993; Mori *et al.*, 1993), which is key for homeostasis of the ER. In this article we summarize the current understanding of this fascinating organelle.

Origin and Function of the ER

The hallmark of eukaryotic cells is the packing of DNA into the nucleus, a compartment that is bounded by the nuclear envelope. The nuclear envelope is continuous with the ER, which suggests that the ER was present in eukaryotic cells right from their ‘inception.’

As the first station along the exocytic pathway, the ER serves as an anticipation of the extracellular world, to prepare molecules to exert their function in a different environment. As such, it is functionally related to the periplasm, the space enclosed between the inner membrane and cell wall of gram-negative bacteria. In analogy, portions of the ER (the so-called cortical ER) are positioned directly below the cell surface also in eukaryotic cells. Both the periplasm and the ER serve to groom proteins that are destined to be part of the cell membranes or to be secreted. Instead of being translocated directly across the plasma membrane, these proteins enter the ER or periplasm first. Here, under the supervision of resident chaperones and enzymes, they attain their native structure before being deployed to the extracellular space. Altogether, these mechanisms warrant efficient production and transport, while simultaneously ensuring the fidelity of the protein secretome, which comprises a third of the eukaryotic proteome, equaling in humans approximately 18 000 gene products (Chen *et al.*, 2005).

Ribosomes that are translating proteins destined for the secretory pathway dock onto the cytosolic face of the ER membrane. These ribosomes give a ‘rough’ appearance to the ER, typical of protein secreting cells. Accordingly, the ribosome-studded parts of the ER therefore are referred to as ‘rough ER,’ while the portion devoid of ribosomes as ‘smooth ER.’ The majority of ‘ER client’ proteins enter co-translationally into the organelle. Some proteins can enter after their synthesis

is completed (posttranslationally). In either case, the proteins traverse the ER membrane through the so-called translocon complex. The latter’s main component, Sec61, has an evolutionary equivalent in gram-negative bacteria (Keenan *et al.*, 2001) that allows proteins to reach the periplasm, which supports the notion that the ER has a periplasmic-like origin.

Next to being the cradle of secretory and cell surface proteins, the ER is the most important site of (membrane) lipid synthesis in the eukaryotic cell (Fagone and Jackowski, 2009). Accordingly, a vast repertoire of enzymes devoted to lipid synthesis resides in the ER. Other organelles depend on membrane lipid supply from the ER, either through vesicular transport or through lipid transfer. The numerous contact points between ER and other organelles likely are sites of such lipid transfer, even though the membranes of the ER and the acceptor organelles are juxtaposed and not continuous. In other organelles the membrane lipids that are derived from the ER often are further derivatized or asymmetrically distributed between membrane leaflets according to need (Vance *et al.*, 1977).

In most eukaryotic cells, the ER also is the major store of intracellular Ca^{2+} ions and most ER resident proteins in fact are low-affinity/high-capacity calcium-binding proteins (Meldolesi and Pozzan, 1998). A wealth of signaling pathways exploits the Ca^{2+} gradient across the ER membrane (Berridge, 2002). Typically, signaling cascades drive the opening of Ca^{2+} channels to sustain a burst of Ca^{2+} through vicinal mitochondria and in the cytosol, which, in turn, serves to propagate the signal. In most cases, there is a rapid reuptake of Ca^{2+} back into the ER, ensuring that Ca^{2+} signaling can start anew. The most sophisticated Ca^{2+} -driven signaling cycles occur at the sarcoplasmic reticulum to sustain muscle contraction (Endo, 1977).

Morphology of the ER

The ER is the most extended organelle in many eukaryotic cells: on average it occupies 10% of the cellular volume, but this figure is larger in plasma cells, exocrine pancreas, and other professional secretory cells. The tubules and sheet-like structures (both rough and smooth) form a continuous membrane system that includes the nuclear envelope (Voeltz and Prinz, 2007). Tubules can be highly curved and branched to form a polygonal network extending throughout the whole

cytosol. ER sheets can be prominent around the nucleus, and may become predominant in some cell types dependent on their function (Figure 2).

Alterations in membrane curvature form the basis of the different morphologies of the ER. For instance, ER tubules are cylindrical with a diameter of 30–100 nm, while sheets are virtually flat. The width of the ER lumen in sheets is restricted to approximately 50–100 nm (Voeltz and Prinz, 2007), but occasionally sac-like structures may develop, bulging from the ER sheet and tubular network, in particular when cells sustain bulk protein secretion or when aberrant proteins aggregate into ER resident deposits (Kopito and Sitia, 2000).

In recent years insights into the mechanisms that are responsible for ER morphology have greatly improved. A number of proteins have been identified that determine its shape. Wedge-like proteins, reticulons and other similar proteins, insert into the ER membrane and dictate the typical curvature found in ER tubules and at the edges of ER sheets, including the nuclear envelope at the sites of nuclear pores (Voeltz *et al.*, 2006). Proteins driving formation of sheet-like structures

include CLIMP-63, a transmembrane protein whose ER luminal domains can homodimerize with another CLIMP-63 molecule protruding into the lumen from the opposing membrane in the ER sheet, and so determining the typical width (Klopfenstein *et al.*, 2001). Other proteins, for example, kinectin and p180, with bulky rod-like structures facing the cytosol seem to be required for stabilizing the flatness of sheets (Lin *et al.*, 2012; Figure 3).

While strictly organized in rough and smooth, tubular, and sheet-like, the ER is highly dynamic at the same time. The network is constantly reshaped through fission and fusion events, in which GTPases of the atlastin and Rab families are involved (Hu *et al.*, 2009; English and Voeltz, 2013). Reshaping of the ER occurs hand in hand with movements of ER elements along the cytoskeleton that are facilitated by motor proteins (Goyal and Blackstone, 2013).

Depending on the cell type and functional requirements, the shape, organization, and size of the ER varies considerably. In muscle cells, for instance, the sarcoplasmic reticulum is a highly organized form of smooth ER devoted to synchronize myofibril contraction (Endo, 1977), while the rough portion

Figure 2 Schematic representation of the ER in animal cells. Reproduced from Goyal, U., Blackstone, C., 2013. Untangling the web: Mechanisms underlying ER network formation. *Biochimica et Biophysica Acta* 1833, 2492–2498.

Figure 3 Wedge-shaped proteins such as reticulons facilitate membrane curvature in ER tubules or at edges of sheets. Spacers such as CLIMP-63 maintain thickness of sheets. Reproduced from Goyal, U., Blackstone, C., 2013. Untangling the web: Mechanisms underlying ER network formation. *Biochimica et Biophysica Acta* 1833, 2492–2498.

of the ER is marginal. In liver cells, the smooth ER is also extensively developed and a major site of detoxifying and synthetic enzymes. In professional secretory cells such as thyrocytes that produce thyroglobulin, acinar cells, which produce digestive enzymes, etc. the rough ER instead is pre-eminent. Antibody producing plasma cells are prototypes of cells with an expanded rough ER (Figure 4).

Membrane Contact Sites of the ER with Other Organelles

Subdomains of the ER make close contact with virtually all other cellular structures, foremost with the nucleus, as the nuclear envelope is continuous with the ER. Contacts of ER

Figure 4 Electron micrograph of a plasma cell, which has an expanded ER to sustain antibody production and secretion. Courtesy of the late Dr. Carlo E. Grossi.

with other organelles are maintained by various tethering complexes that form a bridge between the apposing membranes. ER-plasma membrane contacts are predominant in yeast in which cortical ER represents up to 50% of the organelle. In metazoans ER-plasma membrane contacts are less abundant, but the interaction between STIM in the ER membrane and Orai in the plasma membrane is of particular interest. Together, STIM and Orai mediate store-operated Ca^{2+} entry from the extracellular space across both membranes into the ER lumen (Stefan *et al.*, 2013; Figure 5).

Likewise, protein-mediated tethering of ER to mitochondria sustains close contacts, which are referred to as mitochondria-associated membranes (MAM). In metazoans, these ER-mitochondria contact sites are key for Ca^{2+} transfer and, thus, for signaling: the opening of IP_3 receptor channels at the MAM leads to Ca^{2+} efflux, which is readily imported into the mitochondrial matrix through porins and mitochondrial calcium uniporters (MCUs) to initiate signaling. Excess Ca^{2+} is pumped back from the cytosol into the ER by SERCA (sarco-endoplasmic reticulum Ca^{2+} ATPase) or across the PM by PMCA (plasma membrane Ca^{2+} ATPase) (Figure 5). Ca^{2+} signaling activates some enzymes of the Krebs cycle and, thus, is key for overall metabolism. Yet, unrestrained Ca^{2+} transfer to mitochondria initiates apoptosis (Naon and Scorrano, 2014).

While Ca^{2+} shuttling through ER-mitochondria contacts seems less important in yeast, the contact sites are key for lipid transfer in all eukaryotic cells (Helle *et al.*, 2013). Mitochondria do not synthesize membrane lipids and there is no vesicular transport or any other membrane continuity between mitochondria and the endomembrane system. Thus, mitochondria must be furnished with membrane lipids through lipid transfer proteins. Yet, so far it remains unclear how the lipid transfer process at the MAM is organized.

The ER establishes tether-mediated contacts also with the Golgi, lysosome, and endosomes. Their main function seems

Figure 5 Organization of Ca^{2+} signaling through ER-PM and ER-mitochondria contact sites. Blue represents the local $[\text{Ca}^{2+}]$. A Ca^{2+} gradient is established by SERCA (red) and PMCA (yellow) pumps that pump Ca^{2+} ions from the cytosol into the ER or, respectively, into the extracellular space. ER-PM contacts facilitate replenishing of Ca^{2+} stores in the ER from the extracellular space. STIM (dark green) tethers the ER membrane to the PM at sites where Orai channels are, such that little Ca^{2+} leaks to the cytosol proper. Ca^{2+} is released from the ER through IP_3R channels (tan) mostly at sites, where tethers such as mitofusin (orange) maintain close ER-mitochondria contacts. Ca^{2+} is readily taken up by mitochondria via VDAC (Voltage-dependent anion channels)/Porin (blue) and MCU (light green) channels. Adapted from Helle, S.C., Kanfer, G., Kolar, K., *et al.*, 2013. Organization and function of membrane contact sites. *Biochimica et Biophysica Acta* 1833, 2526–2541.

Figure 6 Proteins destined for the secretory pathway display an N-terminal signal peptide, which is recognized by SRP. The ternary complex of the ribosome, the nascent chain, and SRP is recognized by the SRP receptor and docks onto the translocon, whereupon co-translational translocation into the ER begins.

Figure 7 Topology of ER client proteins. From many ER client proteins the signal peptide (light blue) is removed by signal peptidase (scissors). If the protein has no other hydrophobic stretch, it will be a soluble protein. If the protein has one or more hydrophobic stretches (green) it will be membrane embedded. Tail-anchored proteins have negligible ectodomains at the C-terminus. Some proteins obtain a GPI-anchor, consisting of lipid moieties (wiggled lines) of phosphoinositol (yellow hexagon) that allow membrane embedding coupled via glucosamine (green square), three mannose moieties (pink) and phosphoethanolamine to the polypeptide chain.

to be the transfer from the ER of specific lipids that are in shortage in the target membranes (Helle *et al.*, 2013). Overall storage of lipids takes place in lipid droplets, and it comes as no surprise that lipid droplets are intimately linked with the ER as well (Xu *et al.*, 2012). The ER moreover is the source of membrane lipids for the peroxisome. While *de novo* peroxisome formation initiates with pre-peroxisomal structures derived from the ER (van der Zand *et al.*, 2012), it is unclear whether mature peroxisomes require lipid transfer from the ER through contact sites. Finally, it is still highly debated what is the source of autophagic membranes, which also may turn out to originate either directly or indirectly from the ER.

Translocation and Membrane Embedding of ER Client Proteins

Most client proteins enter the ER co-translationally by virtue of a hydrophobic signal peptide generally located at their

N-termini (Blobel and Dobberstein, 1975). As such, the signal peptide emerges first from the ribosome during translation, whereupon it binds to the signal recognition particle (SRP) (Walter *et al.*, 1981). SRP binding temporarily arrests elongation of the nascent polypeptide and guides the translating ribosome to the SRP receptor, which is associated with the translocon complex (Gilmore *et al.*, 1982). The net result is that translation is now coupled to translocation (Figure 6). The hydrophobic signal peptide is laterally released from the translocon into the ER membrane, while the remainder of the ER client nascent chain reels into the ER lumen with the assistance of resident chaperones (Tyson and Stirling, 2000). Often the signal peptide is then removed by signal peptidase (Blobel and Dobberstein, 1975), but when it is not cleaved off, the signal peptide serves as a membrane anchor (Figure 7).

Translocation continues unless the translocon encounters another hydrophobic stretch in the nascent chain. In that case, again, elongation slows down as the newly made hydrophobic segment is laterally released into the ER membrane to serve as

a transmembrane domain. The remainder of the nascent chain will then be cytosolic unless the translocon encounters yet again a hydrophobic stretch, in which case this segment also will be embedded into the ER membrane. The next portion of the nascent ER client will then enter the ER lumen again, etc. As such, multiple membrane spanning proteins are 'stitched' into the ER membrane and the topology is determined of cytosolic domains, transmembrane domains, and the so-called ectodomains inside the ER lumen. Depending on the 'topogenesis' membrane spanning proteins can be oriented with their N-terminus inside or outside the ER lumen. The first are referred to as type I membrane proteins and the latter as type II (Goder and Spiess, 2001; Figure 7).

A few examples are known of small proteins that traverse the translocon when they are fully synthesized, including the honeybee venom precursor (Zimmermann and Mollay, 1986). To sustain such posttranslational translocation, dedicated accessory proteins of the translocon complex, including Sec63, are required (Lang *et al.*, 2012). Also tail-anchored proteins are posttranslationally inserted into the ER membrane, because the hydrophobic domains that will serve as membrane anchors are at the C-terminus, and thus emerge from the ribosome only once these proteins are already fully synthesized (Figure 7). For tail-anchored protein insertion into the ER membrane TRC-40 (Get3 in yeast) is key to shuttle them from the cytosol to a receptor complex/insertion machinery in the ER membrane, consisting of WRB and CAML (Get1/Get2 in yeast) (Schuldiner *et al.*, 2008; Wang *et al.*, 2014).

Posttranslational Modifications of ER Client Proteins

Besides proteolytic cleavage of the signal peptide, three other common posttranslational modifications of client proteins (or rather their ectodomains) are special to the ER: N-linked glycosylation, insertion of disulfide bonds, and addition of glycolipid tail anchors. Client proteins may obtain in the ER a glycosylphosphatidylinositol (GPI) anchor covalently attached to their C-termini (Udenfriend and Kodukula, 1995). This glycolipid moiety is another means to ensure that the client protein remains associated with the membrane (Figure 7).

Like in the bacterial periplasm, free cysteine residues of client proteins are oxidized in the ER such that two cysteine residues are covalently linked to each other (Figure 8). Disulfide bonds can be formed within (intrachain disulfides) or between (interchain disulfides) client proteins. The latter are important in stabilizing multimeric proteins. Tightly regulated disulfide interchange reactions, driven by protein relays, regulate oxidative protein folding, a process intimately linked to redox signaling, in that reactive oxygen species can be generated as byproducts (Tu and Weissman, 2004).

ER client proteins moreover can be glycosylated when an asparagine (N) residue is followed by any residue but proline (X) and then a serine or threonine (NXS/T). The glycan, consisting of three glucoses, nine mannoses, and two *N*-acetyl glucosamines (Figure 9), is transferred en bloc from dolichol precursors. Glycosylation occurs most often co-translationally, as soon as a site emerges in the ER lumen and is recognized by oligosaccharyl transferase (Helenius and Aebi, 2004). Not all potential acceptor sites are always used, however. In the prion

Figure 8 ER client proteins obtain disulfide bonds. PDI or PDI-like proteins catalyze the reaction, but also rearrange aberrant disulfide bonds.

protein, for instance, glycosylation competes with disulfide bonding and GPI addition, which increases the number of isoforms that can be produced (Orsi and Sitia, 2007). Soon after their en bloc addition to proteins in the ER, N-linked glycans are sequentially trimmed by resident glucosidases and mannosidases (Ellgaard and Helenius, 2003), providing important cues for quality control (see below).

Several other posttranslational modifications can occur in the ER. Some ER client proteins obtain mannose moieties that are covalently linked to serine or threonine residues. Such O-mannosylation occurs predominantly in serine/threonine-rich domains of ER client proteins (Praisman and Wells, 2014). Relevant to human pathology is hydroxylation of proline and lysine residues in collagens. The responsible ER resident hydroxylases use vitamin C as an obligatory cofactor, which nicely explains the pathogenesis of scurvy.

Protein Folding in the ER

Newly synthesized proteins progressively adopt conformations that are energetically more favorable, until the correctly folded 'native' conformation is reached. Anfinsen's axiom that folding information is contained in the protein sequence undoubtedly holds true (Anfinsen, 1973). Yet, metastable nonnative

Figure 9 ER client proteins obtain *N*-glycans, consisting of 2 GlcNAc moieties (green squares), 9 mannose moieties (pink circles), and 3 glucose moieties (blue diamonds). Glucoses are trimmed by glucosidases I and II and monoglucosylated glycans allow association with lectin chaperones – calnexin (CNX) is shown here – Gluc II then removes the last glucose and the ER client will either go to ER exit sites (if successfully folded) or it will re-associate with CNX, because UGGT re-added a glucose. Repetitive (de-)glucosylation cycles may occur until mannose trimming leads to association with lectins like EDEM that target the client for ERAD by the proteasome. Adapted from Mitchell, W.B., Li, J., French, D.L., Collier, B.S., 2006. α IIb β 3 biogenesis is controlled by engagement of α IIb in the calnexin cycle via the N15-linked glycan. *Blood* 107, 2713–2719.

conformations may be adopted, often hindering productive completion of the folding process. This phenomenon is particularly evident when folding goes hand in hand with disulfide bond formation. Not surprisingly, therefore, Anfinsen identified protein disulfide isomerase (PDI) as a crucial catalyst through his pioneering work on RNase folding (Gold-enberger *et al.*, 1963). PDI can reshuffle disulfide bonds such that client proteins efficiently attain their native structure (Figure 8). The folding of ER client proteins often is particularly complex and, hence, the ER hosts an impressive repertoire of molecular chaperones and foldases.

Classical molecular chaperones in the ER are functionally similar to counterparts in other folding environments such as the HSP70 family member BiP (Kar2 in yeast). Similar to other HSP70s in the cytosol, mitochondria, etc., BiP transiently binds hydrophobic patches of ER client proteins and thereby protects them from undergoing inappropriate interactions with other proteins (Mayer and Bukau, 2005). BiP is an ATPase and cycles of client binding and release require ATP hydrolysis. Several J-domain containing co-chaperones (ERdj1–5), but also nucleotide exchange factors, modulate BiP's activity and help determine its clientele (Shen *et al.*, 2002; Steel *et al.*, 2004). A distant HSP70-like relative in the metazoan ER is GRP170 that often acts in tandem with BiP, most notably assisting translocation of client proteins (Steel *et al.*, 2004). Similarly, GRP94, the HSP90 equivalent in the metazoan ER, guides maturation of a limited repertoire of client proteins likely with assistance from co-chaperones of the CNPY family (Eletto *et al.*, 2010; Liu *et al.*, 2010). Surprisingly perhaps, the ER lacks members of small HSP (although they are present in plant ER) and the HSP60 families of chaperones.

Foldases are enzymes that catalyze folding steps. For the folding of many client proteins *cis/trans*-isomerization of

proline residues is the rate-limiting step. To smoothen the process of prolyl isomerization, the ER harbors a number of peptidylprolyl isomerases (PPIases), similar to other folding compartments. The most prominent PPIase in the ER is cyclophilin B, but also a few members of the FKBP family are present (Galat, 2003).

Unique to the ER are foldases of the PDI family that catalyze formation of disulfide bonds (Figure 8). Dependent on the cell type, various PDI family members are present, each likely with (slightly) distinct oxidative properties and clientele. Notable PDI family members include Erp57, Erp72, and P5 (Appenzeller-Herzog and Ellgaard, 2008). As in the case of RNase, PDIs can reshuffle disulfide bonds, exchanging aberrant for native disulfide bonds. The *de novo* disulfide bond formation requires transfer of disulfide bonds from PDIs to client proteins. This process entails that PDIs are constantly reoxidized. In yeast, reoxidation of PDI is the exclusive task of Ero1, which uses O₂ as terminal electron acceptor, thereby generating H₂O₂ (Tu and Weissman, 2004). In metazoans, ERO1 proteins share the burden of generating reoxidizing equivalents to sustain disulfide bond formation with peroxiredoxin IV, glutathione peroxidases 7 and 8, and vitamin K epoxide reductase (Bulleid and Ellgaard, 2011).

The glycans play a unique role in the folding process of ER client proteins. Once the first two glucose moieties are removed by glucosidases, lectin chaperones of the calnexin/calreticulin (CNX/CRT) family associate with the monoglucosylated glycans to promote folding. They release the client when also the final glucose is removed, but if the folding is incomplete, the glycan becomes reglucosylated by UGGT allowing another cycle of CNX/CRT association (Helenius and Aebi, 2004; Figure 9). Also the mannose moieties are progressively trimmed until the glycan structure is eventually recognized by lectins of the EDEM

and OS9 families and dispatched to the cytosol for proteasomal degradation (Hosokawa *et al.*, 2001; Christianson *et al.*, 2008). In this way, molecules that did not have enough time to fold are spared from degradation, while those client proteins that linger in the ER for too long because they fail to fold are retro-translocated to the cytosol. Here, they are deglycosylated, ubiquitinated, and, finally, degraded by the proteasome, a process referred to as ER-associated degradation (ERAD) (Werner *et al.*, 1996). Rarely, misfolded clients may escape ERAD and accumulate instead in the ER, sometimes even forming aggregates. Autophagy may serve as a backup removal mechanism. Yet, persistent accumulation of misfolded ER clients often leads to ER storage diseases (Anelli and Sitia, 2010).

In general, however, the combined efforts of the ER resident chaperones and foldases promote productive folding, and, at the same time, ensure through their persistent binding

that immature clients are retained in the ER. Only when clients are fully folded (and properly assembled in case of multimeric proteins) do all chaperones release and allow exit of clients to travel further along the secretory pathway. As such, stringent quality control is exerted on the secretory proteome (Ellgaard and Helenius, 2003; Anelli and Sitia, 2008).

Export from and Retrieval to the ER

Once client proteins are correctly folded, they are sorted to ER exit sites. Some clients team up with dedicated cargo receptors to promote this sorting process. Notable examples include the lectin ER–Golgi intermediate compartment (ERGIC-53) (Appenzeller *et al.*, 1999). At ER exit sites membrane curvature is promoted through the buildup of a coat. Key players in this

Figure 10 ER export and retrieval. Fully folded ER client proteins exit from the ER at ER exit sites, where they are packaged into COPII coated vesicles. Some clients are specifically recruited for exit by cargo receptors, while other clients enter these vesicles by bulk flow. The COPII vesicles bud from ER exit sites and travel through anterograde transport to the cis-Golgi. The vesicles dock through tethering of the two membranes and fuse through the action of SNAREs on both vesicle (v) and target (t) membranes. The cargo is released into the Golgi and the COPII coat dissociates. Retrograde transport is facilitated by COPI coated vesicles, that let cargo receptors and KDEL receptors travel back to the ER. KDEL receptors pick up ER chaperones and folding enzymes that display a KDEL (-like) tetrapeptide at their C-terminus.

Figure 11 Overview of how UPR pathways aim for ER homeostasis or give way to apoptosis.

process are the components of coat protein complex II (COPII) and the GTPase Sar1 (Barlowe *et al.*, 1994). GTP hydrolysis guides both the installment of the coat and the eventual budding from the ER of COPII-coated vesicles that contain the client proteins (Kuehn *et al.*, 1998; Figure 10). The vesicles then undergo anterograde transport along the secretory pathway, traveling via the ERGIC, the Golgi apparatus, the *trans*-Golgi network before reaching the plasma membrane as the final destination. Through the endocytic pathway, i.e., via endosomes to lysosomes, proteins may travel back into the cell. The secretory and endocytic pathways therefore form a continuous endomembrane system that is interconnected through vesicular transport. Accordingly, almost all proteins of the endomembrane system originate from the ER.

Specific SNARE proteins mark transport vesicles to define their origin and they team up selectively with those SNARE proteins that mark the designated target membrane. Rab family members further assist in ensuring proper delivery of vesicles. The SNAREs on the two membranes combined drive fusion of the vesicle with the target organelle (ERGIC or Golgi) and release of the client protein cargo into the next station along the secretory pathway (Sudhof and Rothman, 2009; Figure 10). While most ER clients that are subunits of multimeric complexes need to oligomerize first in order to exit the ER, some assembly steps may take place in the ERGIC, as is the case for oligomerization of immunoglobulin M (Anelli *et al.*, 2007). In principle, folding and assembly are thus fully completed when clients arrive in the Golgi. In downstream compartments of the secretory pathway, N-linked glycans often are further modified in several ways, yielding varied complex glycan structures. In the *trans*-Golgi network, some clients are even proteolytically cleaved by furin(-like) endoproteases to reach their mature state.

If immature client proteins untimely exit the ER, they usually are retrieved from further stations along the secretory pathway through retrograde transport. The ER chaperones and foldases in small numbers do travel to the Golgi, where they can pick up escapee clients. The chaperones carry at their C-terminus a lysine aspartate glutamate leucine (KDEL) or related tetrapeptide (Munro and Pelham, 1987), which is recognized by KDEL receptors in the Golgi. The ternary client-chaperone-KDEL receptor complex is then sorted to COPI-coated vesicles that travel back to the ER for further client folding attempts (Lewis and Pelham, 1992; Figure 10). The pH gradient between the ER and Golgi contributes in regulating transport and quality control. ERGIC-53 captures glycoproteins in the ER releasing them in the more acidic pH in the Golgi, where instead the chaperone ERp44 and KDEL receptors are activated (Wilson *et al.*, 1993; Vavassori *et al.*, 2013). The ternary complex formed with clients is retrieved back to the ER, whose neutral pH favors dissociation. It is thought that KDEL receptors keep track of the protein flux exiting the ER and accordingly act as signaling devices (they are structurally and functionally similar to GPCRs), to drive adaptations in vesicular transport capacity to and from the Golgi (Pulvirenti *et al.*, 2008).

ER Homeostasis

To maintain homeostasis, the ER folding capacity or efficiency must be adjusted to the folding load, which may vary during differentiation or due to changing environmental cues (drugs or cofactor deficiencies). In essence, the ER perceives accumulation of aberrant or orphan proteins that cannot complete their folding schedule. The intricate sensing mechanisms that

monitor load and that trigger a response to 'ER stress' are collectively referred to as the UPR pathways (Ron and Walter, 2007). In metazoans, the UPR is not only key for mitigating ER stress, but also is essential for development and maintenance of professional secretory cells, for instance during plasma cell differentiation (Iwakoshi *et al.*, 2003) or in pancreatic β -cell physiology (Harding *et al.*, 2001).

Insufficient protein folding capacity in the ER is detected by UPR transducers of the IRE1, PERK, and ATF6 families (Ron and Walter, 2007). They all are transmembrane proteins with an ER luminal stress sensing domain and a cytosolic effector domain. ATF6 proteins – which are exclusive to metazoans – travel from the ER to the Golgi. Here, cleavage by a resident protease allows the ATF6 cytosolic domain to detach, such that it can relocate to the nucleus, where it activates transcription of target genes (Mori, 2009). IRE1 proteins – which are conserved in all eukaryotes – initiate the non-conventional splicing of *xbp1* mRNA (*HAC1* in yeast), whereupon the spliced mRNA is translated into another transcription activator of distinct UPR target genes (Ron and Walter, 2007). PERK – exclusive to animal cells – phosphorylates eIF2 α , which causes translational attenuation, thereby blocking further entry of ER clients. Paradoxically, synthesis of some other proteins that further control the response (e.g., ATF4 and CHOP) is enhanced when eIF2 α is phosphorylated (Ron and Walter, 2007).

UPR target genes include a full repertoire of ER chaperones and foldases, but also enzymes for membrane lipid synthesis that together sustain expansion of the ER and its folding capacity. Other UPR targets are ERAD components, which enhance the clearance of misfolded clients from the ER. IRE1 proteins may also contribute to the curtailing of the folding load in the ER through degradation of mRNAs other than *xbp1*, a process referred to as regulated Ire1-dependent decay (Hollien and Weissman, 2006). Finally, excess or damaged ER with its contents can be targeted for removal by autophagy (Bernales *et al.*, 2006). Such 'ERphagy' may also be key to downsize the ER when cells are recovering from ER stress or to sustain balanced ER expansion in professional secretory cells (Pengo *et al.*, 2013).

Yet, when all adaptive measures are exhausted, the UPR induces apoptosis, for instance through persistent activation of PERK and its downstream effector CHOP. Also IRE1 can invoke pro-apoptotic pathways (Ron and Walter, 2007). Maladaptive ER stress responses can lie at the basis of a growing list of pathologies. For example, excessive insulin synthesis and a corresponding 'overzealous' UPR in pancreatic β -cells lead to their demise and, hence, type 2 diabetes (Oyadomari *et al.*, 2002). A schematic overview of how the UPR orchestrates ER homeostasis is shown in Figure 11.

Perspectives

Many questions remain open concerning the ER. How do cells set and maintain an optimal ratio between ER subdomains? What are all the distinguishing components of subdomains and the plethora of ER contact sites? How is production in the ER factory coordinated with the flux of proteins through the secretory pathway? How do developmental cues determine

that the ER specializes in one of its many manifestations? Which are the cues that activate and direct ERphagy? Can we reconstruct the ER in a test tube? Can we create model cells with a 'tailor-made' ER for biotechnological purposes? It is clear that the ER has a multitude of surprising and exciting features in store that remain to be discovered.

Intermediate Compartment: A Sorting Station between the Endoplasmic Reticulum and the Golgi Apparatus

J Saraste and M Marie, University of Bergen, Bergen, Norway

© 2016 Elsevier Inc. All rights reserved.

Glossary

Anterograde transport Transport from endoplasmic reticulum (ER) toward the cell surface.

ER exit sites ER subdomains specialized in the export of newly synthesized molecules.

Golgi stacks Stacks of flat membrane-bound cisternae. The mammalian Golgi stacks contain 4–8 cisternae.

Lumen The space inside a membrane-bound structure.

Microtubules Cytoskeletal filaments that provide tracks for motor-dependent long-distance transport of organelles and transport carriers.

Pleomorphic Variable in size and shape.

Retrograde transport Transport from post-ER compartments toward the ER.

Saccule Membrane-bound structure with a large lumen.

Vesicle Membrane-bound structure with a small lumen.

Introduction

Newly synthesized proteins and lipids leave the endoplasmic reticulum (ER) at specialized transitional regions called ER exit sites (ERES) (Jamieson and Palade, 1967; Sesso *et al.*, 1994; Bannykh *et al.*, 1996; Hammond and Glick, 2000; Tang *et al.*, 2005) and enter the intermediate compartment (IC) that has been shown to operate as an obligatory a post-ER sorting station in the early biosynthetic-secretory trafficking of mammalian cells. From the IC they are typically transported to the cisternal stacks of the Golgi apparatus, prior to their delivery to the different organelles of the endomembrane system or secretion to the extracellular space. Bidirectional ER–Golgi trafficking involves the sequential operation of membrane-bound coat protein II (COPII) and COPI coats (Aridor and Balch, 1996; Scales *et al.*, 1997; Stephens *et al.*, 2000). ER-derived COPII vesicles mediate forward (anterograde) transport, while IC- and Golgi-derived COPI vesicles are thought to act in the opposite (retrograde) direction (Lee *et al.*, 2004; Rabouille and Klumperman, 2005). Retrograde transport also involves COPI-independent routes (Kano *et al.*, 2009).

Despite the conservation of the transport machineries (such as the COP coats), the organization of the ER–Golgi interface varies in different eukaryotic cells. For example, in plants, certain yeasts, and the fruit fly *Drosophila melanogaster*, the individual Golgi stacks lie next to the widespread ERES, establishing units for short range ER–Golgi communication. By contrast, in animal cells the Golgi stacks are linked together into a continuous ribbon around the microtubule-organizing center (MTOC)/centrosome, whereas the ER extends throughout the cytoplasm. Hence, a large proportion of the ERES reside at the cell periphery and ER–Golgi trafficking depends on the long distance movements of the IC elements along MT tracks (Saraste and Svensson, 1991; Presley *et al.*, 1997; Scales *et al.*, 1997; Brandizzi and Barlowe, 2013; Day *et al.*, 2013). Thus, it has been proposed that the IC represents a late evolutionary invention, which developed to meet the special sorting, transport and recycling requirements of the large-sized animal cells, but lacks lower eukaryotes. However, results showing that the IC constitutes an extensive membrane system

that can be compared with the endosomal network in complexity, are questioning this view.

Historical Perspective

15 °C Compartment

Electron microscopic (EM) studies using a temperature-sensitive mutant of Semliki Forest virus (SFV ts-1) to synchronize the transport of viral membrane glycoproteins from ER to the plasma membrane (PM) showed that when the cells are shifted from 39 °C to 15 °C the proteins exit the ER, but accumulate in vacuoles/saccules (up to 0.5 µm in diameter), tubules, and vesicles in the *cis*-Golgi region and more peripheral locations (Saraste and Kuusmanen, 1984). By light microscopy (LM) the proteins were localized at 15 °C to scattered globular structures in the cytoplasm, a pattern distinct from that of ER or Golgi (Kuusmanen and Saraste, 1989). The transport block was readily reversible, and the proteins entered the Golgi stacks and reached the PM following the transfer of cells from 15 °C to 28 °C, showing that these structures are normal transport intermediates.

Studies employing a similar mutant of vesicular stomatitis virus (VSV tsO45) showed that the '15 °C compartment' also acts as a way station during the transport of the VSV G glycoprotein (Balch *et al.*, 1986; Bonatti *et al.*, 1989; Schweizer *et al.*, 1990; Duden *et al.*, 1991; Lotti *et al.*, 1992). Like the SFV proteins, the G-protein was found to maintain its ER-type high-mannose glycans at 15 °C, indicating lack of processing by Golgi enzymes. Furthermore, cell fractionation experiments showed that newly synthesized secretory proteins are arrested in a post-ER location when pancreatic exocrine cells are kept at 16 °C (Saraste *et al.*, 1986). Live cell imaging of green fluorescent protein (GFP) equipped with an ER targeting signal (ssGFP) and EM studies of procollagen and growth hormone constructs verified that the transport of membrane and secretory proteins is similarly affected at 15–16 °C (Blum *et al.*, 2000; Volchuk *et al.*, 2000; Trucco *et al.*, 2004). In addition, the transport of virus glycoproteins and cholesterol appears to

be blocked at the same site at this temperature (Urbani and Simoni, 1990; Heino *et al.* 2000).

Coronavirus Budding Compartment

EM of mouse hepatitis virus (MHV)-infected cells showed that the budding of progeny virus initially takes place at tubulovesicular membranes located in the transitional region between the ER and the Golgi apparatus (Tooze *et al.*, 1984). The first step of O-glycosylation, the attachment of N-acetyl-galactosamine (GalNAc) to the viral membrane (M) glycoprotein, was suggested to occur in this compartment, causing its reactivity with the lectin Helix pomatia, which specifically binds GalNAc (Tooze *et al.*, 1988; Krijnse-Locker *et al.*, 1994). Subsequent studies showed that the intracellular maturation of various coronaviruses occurs at the same budding site, which corresponds to the IC (Klumperman *et al.*, 1994).

Salvage Compartment

The discovery of the lys-asp-glu-leu tetra-peptide (KDEL)-motif in abundant, luminal ER proteins lead to the proposal that the 15 °C/budding compartment is the post-ER site from which these proteins are retrieved to the ER (Munro and Pelham, 1987; Warren, 1987; Pelham, 1989). The first mammalian KDEL-receptor, a multispanning membrane protein, was identified and shown to predominantly localize to the IC and *cis*-Golgi (Lewis and Pelham, 1990; Tang *et al.*, 1993; Griffiths *et al.*, 1994; Orci *et al.*, 1997). Also, KDEL proteins, such as the immunoglobulin binding protein (BiP/GRP78), glucose-regulated protein of 94 kDa (GRP94), protein disulphide isomerase (PDI) and calreticulin (CR), are present in the IC (Griffiths *et al.*, 1994; Connolly *et al.*, 1994; Zuber *et al.*, 2001; Ying *et al.*, 2002; Breuza *et al.*, 2004). Following binding to their receptor, the proteins are retrieved to the ER in COPI vesicles (Orci *et al.*, 1997; Martínez-Menárguez *et al.*, 1999; Majoul *et al.*, 2001). Attachment of the KDEL-motif to lysosomal enzymes and the use of the 15 °C block suggested that the enzyme that initiates the formation of their lysosomal targeting signal (mannose-6-phosphate) resides in the IC (Pelham, 1988; Lazzarino and Gabel, 1988; Dittmer and von Figura, 1999). The cytoplasmic tails of certain type I integral membrane proteins were shown to contain dilysine (KKXX)-motifs, which by directly interacting with COPI coats result in their retrieval from the IC/*cis*-Golgi to the ER (Nilsson *et al.*, 1989; Jackson *et al.*, 1990, 1993; Cosson and Letourneur, 1997).

p58/ERGIC-53/LMAN1

The first endogenous IC markers rat p58 and human ER-Golgi intermediate compartment (ERGIC)-53 (89% homology) were identified by the generation of antibodies against the 16 °C post-ER fraction isolated from pancreatic acinar cells (Saraste *et al.*, 1987) and a Golgi fraction derived from epithelial Caco-2 cells (Schweizer *et al.*, 1988), respectively. The cytoplasmic C-terminal tails of these non-glycosylated, hexameric, type-1 integral membrane proteins (Schindler *et al.*,

1993; Lahtinen *et al.*, 1992, 1996; Neve *et al.*, 2005) contain a KKFF-motif, which interacts with COPII and COPI coats and gives rise to their continuous cycling between ER, IC, and *cis*-Golgi (Kappeler *et al.*, 1997; Tisdale *et al.*, 1997). At 15 °C the recycling of p58/ERGIC-53 to the ER is inhibited and the proteins pile up in the same pre-Golgi structures that contain the SFV or VSV membrane proteins (Schweizer *et al.*, 1990; Saraste and Svensson, 1991; Plutner *et al.*, 1992), verifying that the p58/ERGIC-53 compartment (Figures 1 and 4) is equivalent to the site where cargo is arrested at low temperature.

ERGIC-53 and the related VIP36 were shown to share homology with leguminous plant lectins (Fiedler and Simons, 1994) and to be identical with a mannose-binding protein MR60 of human myelomonocytic (HL60) cells (Arar *et al.*, 1995). The N-terminal domain of p58/ERGIC-53 binds mannose in a calcium-dependent manner (Itin *et al.*, 1996; Velloso *et al.*, 2003; Zheng *et al.*, 2013); hence the name lectin mannose-binding protein 1 (LMAN1). It is the best characterized mammalian cargo receptor, facilitating the COPII vesicle-mediated export of a subset of soluble glycoproteins from the ER (Nichols *et al.*, 1998; Appenzeller *et al.*, 1999; Hauri *et al.*, 2000).

Compositional Aspects

Most well-characterized IC proteins are components of the transport machinery. Many of them cycle at the ER-Golgi boundary and are also found in *cis*-Golgi, supporting the view of the IC as a transient structure (see below). In fact, EM studies showing the specific metal (osmium) staining of the IC and *cis*-Golgi provided the first indication of their compositional similarity (Friend and Murray, 1965; Rambourg *et al.*, 1974). However, the fungal compound brefeldin A (BFA) helps to discriminate between IC and Golgi components. It releases COPI coats, disassembles the Golgi stacks and redistributes Golgi components to the ER, whereas cycling proteins (such as p58/ERGIC-53/LMAN1 and the KDEL-receptor) are arrested in the drug-resistant IC elements (Lippincott-Schwartz *et al.*, 1990; Saraste and Svensson, 1991; Tang *et al.*, 1995b; Füllekrug *et al.*, 1997; Ward *et al.*, 2001; Marie *et al.*, 2009). The BFA resistance of the IC has been utilized for its proteomics analysis (Breuza *et al.*, 2004), and indicates its stability.

The p24 Protein Family

Like p58/ERGIC-53, the p24 family proteins contain motifs for COPII and COPI binding, resulting in their cycling between the ER, IC, and *cis*-Golgi (Rojo *et al.*, 1997; Dominguez *et al.*, 1998; Blum *et al.*, 1999; Gommel *et al.*, 1999; Strating and Martens, 2009). As abundant type-1 transmembrane proteins they participate in the biogenesis of COPI vesicles (Stamnes *et al.*, 1995; Majoul *et al.*, 2001; Beck *et al.*, 2009), but have also been implicated in tubulation (Simpson *et al.*, 2006) and the formation of membrane domains (Lavoie *et al.*, 1999; Emery *et al.*, 2003). Studies in yeast first suggested their function as receptors for the exit of

Figure 1 (a) Immunofluorescence LM localization of p58/ERGIC-53 in baby hamster kidney, (b) mouse myeloma, (c) rat neuroendocrine PC12, and (d) human HeLa cells. The protein marks the IC elements accumulating in the perinuclear Golgi region (asterisks), scattered throughout the cytoplasm, and located close to the PM (arrows). The reticular staining indicates the ER pool of p58/ERGIC-53, which varies in the different cell types. Nu, nucleus. Bar: 10 μ m.

glycosylphosphatidylinositol (GPI)-anchored proteins from the ER (Schimmöller *et al.*, 1995).

suggesting that the IC represents the main point for recycling (Martínez-Menárguez *et al.*, 1999).

COPI Coats

The COPI coats are mainly recruited to the cytoplasmic surface of IC and *cis*-Golgi membranes, but also associate with the lateral rims of the Golgi stacks (Duden *et al.*, 1991; Oprins *et al.*, 1993; Griffiths *et al.*, 1995; Orci *et al.*, 1997; Klumperman *et al.*, 1998). COPI vesicle budding depends on the activation of small GTPases of the ADP-ribosylation factor (Arf) family (Popoff *et al.*, 2011). The guanine nucleotide exchange factor (GEF) of these Arfs, GBF1, is the master regulator of COPI recruitment and the target of BFA (Niu *et al.*, 2005). It localizes to the IC and *cis*-Golgi and plays a key role in ER-to-Golgi trafficking (Kawamoto *et al.*, 2002; Garcia-Mata *et al.*, 2003; Zhao *et al.*, 2006; Szul *et al.*, 2007). GBF1 knock down or specific inhibition by Golgicide A releases COPI coats and arrests the VSV G-protein in the IC, indicating its involvement in anterograde IC-to-Golgi transport (Manolea *et al.*, 2008; Sáenz *et al.*, 2009). However, the prevailing view is that the main function of COPI vesicles is to recycle membrane and selected proteins to the ER. In pancreatic exocrine cells approximately 70% of the coats associate with the VTCs,

Rab1 and Rab2

The roles of two GTPases of the large Rab family, Rab1 and Rab2, in ER–Golgi trafficking are relatively well understood (Plutner *et al.*, 1991; Tisdale *et al.*, 1992). Both interact with multiple effectors suggesting that they coordinate successive transport steps (Barnekow *et al.*, 2009). The association of Rab1 with the cytoplasmic surface of IC and *cis*-Golgi membranes, and its absence from the ER, has been demonstrated by EM (Griffiths *et al.*, 1994; Saraste *et al.*, 1995; Satoh *et al.*, 2003; Marie *et al.*, 2012; Figure 2). The two Rab1 isoforms, Rab1A and RAB1B (93% homology), are recruited to IC membranes at ERES, show similar localizations by LM (Mochizuki *et al.*, 2013; Figure 3(a)), but seem to play distinct roles in tubular and vesicular (long and short range) trafficking within the IC. Accordingly, live cell imaging and cell fractionation have shown that Rab1A mainly associates with IC tubules (Sannerud *et al.*, 2006; Marie *et al.*, 2009), while Rab1B interacts with GBF1 and evidently modulates COPI recruitment to globular IC domains (Alvarez *et al.*, 2003; Monetta *et al.*, 2007; see below). Also, Rab1A is specifically

Figure 2 Immunogold EM localization of Rab1 in the Golgi region of a normal rat kidney (NRK) cell. The 15 nm gold particles predominantly label pleiomorphic IC elements at the *cis*-face of the Golgi stacks. A saccule (asterisk) and a vesicular tubular cluster (VTC; dashed area) are indicated. The micrograph was kindly provided by Dr. Karin Pernet-Gallay (University Joseph Fourier, Grenoble, France). Bar: 3 μ m.

phosphorylated at mitosis (Bailly *et al.*, 1991), correlating with the cessation of tubular IC dynamics, whereas COPI-mediated vesicular transport continues (Marie *et al.*, 2012). Rab1A can functionally replace Ypt1, which coordinates two-way ER–Golgi trafficking in the yeast *Saccharomyces cerevisiae* (Haubruck *et al.* 1989; Segev, 2001; Kamena *et al.*, 2008).

Rab2 has been localized to IC and *cis*-Golgi membranes (Chavrier *et al.*, 1990; Lotti *et al.*, 1992) and proposed to regulate the formation of retrograde COPI vesicles that contain p58/ERGIC-53 (Tisdale, 1999). It has also been implicated in the recruitment of the motor protein dynein to IC membranes and the association of IC elements with MTs (Tisdale *et al.*, 2009; see below).

Tethers and Soluble NSF Attachment Protein Receptors

Most of the known Rab1 and Rab2 effectors are cytoplasmically oriented, long coiled-coil proteins, which function in the tethering of vesicle and organelle membranes preceding their soluble NSF attachment protein receptor (SNARE)-mediated fusion (Barnekow *et al.*, 2009; Sztul and Lupashin, 2009). Besides the IC/*cis*-Golgi tethers GM130 and GMAP-210 (Rios *et al.*, 2004), Rab2 has been shown to interact with *medial*- and *trans*-Golgi tethers, suggesting a more widespread function (Short *et al.*, 2001; Sinka *et al.*, 2008). The Rab1 effector p115 is functional already at the peripheral ERES (Alvarez *et al.*, 1999), while GM130 (bound to its membrane anchor GRASP65) cycles between central IC and *cis*-Golgi (Marra *et al.*, 2001) and regulates membrane tethering at a later transport step (Alvarez *et al.*, 2001; Marra *et al.*, 2007). Rab1 also

interacts with the transmembrane tethers golgin-84 and giantin, which appear to act in COPI vesicle trafficking at the lateral rims of the Golgi stacks (Diao *et al.*, 2003; Malsam *et al.*, 2005; Barnekow *et al.*, 2009; Munro, 2011).

The membrane fusion machinery (SNARE proteins) operating in ER–Golgi trafficking in the yeast *Saccharomyces cerevisiae* has been well characterized (Cai *et al.*, 2007; Barlowe and Miller, 2013), whereas the fusion events that take place in mammalian cells remain enigmatic. The determination of the exact fusion steps is complicated by the continuous cycling of the SNAREs in COPI vesicles (Hay *et al.*, 1998; Martínez-Menárguez *et al.*, 2001). In analogy to yeast, Rab1 (Ypt1) has been suggested to recruit p115 (Uso1p) to COPII vesicles at ERES (Allan *et al.*, 2000), followed by the formation of a SNARE complex (Sec22B, membrin, Bet1 and syntaxin 5), which mediates either homotypic fusion of COPII vesicles or their heterotypic fusion with the stationary IC (Zhang *et al.*, 1997; Xu *et al.*, 2000; see below). Another SNARE complex (syntaxin 5, GS28, Bet1 and Ykt6) is involved in a later *cis*-Golgi transport step (Zhang and Hong, 2001).

Structure, Distribution, and Dynamics

By EM the IC elements can be readily distinguished from the ER and Golgi, but share structural similarity with endosomes. They reside close to peripheral and central ERES as clusters of vesicles and tubules (VTCs; Figure 4(f)) that frequently contain COPI coats (Balch *et al.*, 1994; Bannykh *et al.*, 1996; Martínez-Menárguez *et al.*, 1999). However, they display considerable size heterogeneity (Ying *et al.*, 2000) and also include large saccules that are found within the membrane clusters, free in the cytoplasm, or at the *cis*-face of the Golgi stacks (Saraste and Svensson, 1991; Lahtinen *et al.*, 1992; Connolly *et al.*, 1994; Stinchcombe *et al.*, 1995; Ladinsky *et al.*, 1999; Fan *et al.*, 2003; Figures 4(a)–4(e)). These pleiomorphic saccules can accommodate large-sized cargo, such as procollagen or luminal protein aggregates (Volchuk *et al.*, 2000; Trucco *et al.*, 2004; Zuber *et al.*, 2004), and based on correlative microscopy (LM/EM) correspond to many of the mobile carriers that are visible in living cells (Mironov *et al.*, 2003). Like endosomes, they extend narrow tubules and also bind COPI coats, indicating that they represent sites for vesicle budding (Saraste and Kuismanen, 1984; Volchuk *et al.*, 2000; Horstman *et al.*, 2002; Figures 4(c) and 4(d)). The hypertrophy of the saccular domains most likely gives rise to the pre-Golgi vacuoles seen in cells kept at 15 °C (Saraste and Kuismanen, 1992; Trucco *et al.*, 2004).

LM shows the division of the IC into globular and tubular domains (Presley *et al.*, 1998). The former contain anterograde cargo, cargo receptors and COPI coats, most likely corresponding to individual VTCs or free saccules, while the latter are highlighted by Rab1A (Sannerud *et al.*, 2006). The tubules extend from the globular domains (Figure 5). Some of them contain recycling proteins, but lack anterograde cargo, indicating that they function in retrograde transport (Palokangas *et al.*, 1998; Simpson *et al.*, 2006). However, under synchronized conditions cargo is also detected in the tubular domain, due to overload or the existence of different types of

Figure 3 (a) Immunofluorescence LM localization of the two Rab1 isoforms at different phases of the cell cycle. NRK cells stably expressing GFP-Rab1A were stained with monoclonal antibodies against Rab1B (kindly provided by Prof. Angelika Barnekow, University of Münster, Germany). At interphase the proteins colocalize in the Golgi ribbon, the separated pcIC (arrow) and peripheral IC elements (insets). During mitosis (at metaphase), following Golgi disassembly, the isoforms maintain their pericentrosomal co-localization at the spindle poles (arrows). (b) Association of IC elements with MTs. NRK cells were stained for the IC markers Rab1 or p58 and β -tubulin (to visualize MTs). Only the image overlays are shown. The insets show coalignment of IC elements with MTs (arrowheads). See also Marie *et al.*, 2012. Bars: 10 μ m.

IC tubules (Figure 6). For example, incubation of cells at 15–16 °C inhibits the formation of IC tubules, but causes the expansion of the globular domain, while the shift of cells to 37 °C generates tubular networks containing both antero- and retrograde markers (Blum *et al.*, 2000; Ben-Takaya *et al.*, 2005; Simpson *et al.*, 2006). Proliferation of the tubules is induced when COPI function is compromised (Szul *et al.*, 2007; Marie *et al.*, 2009; Ben-Takaya *et al.*, 2010; Tomás *et al.*, 2010; Hamlin *et al.*, 2014), but also occurs under physiological conditions. In differentiating neuroendocrine PC12 cells the Rab1A-positive tubular IC domain expands and the tubules move from the cell body to the forming neurites accumulating in their growth cones (Sannerud *et al.*, 2006; Figure 5). An analogous pathway connects the IC with the leading edge of fibroblasts (Figure 6).

Live imaging of various fluorescent IC markers indicates that the tubules are highly dynamic, while the globular domains are typically more stationary. Due to their differential localization within these domains, the constructs highlight

different aspects of IC dynamics (see below). Long distance ER-to-Golgi transport involves the movement of IC elements from the cell periphery to the central *cis*-Golgi region, resulting in the division of the IC into spatially distinct early (ERES-adjacent) and late (*cis*-Golgi-adjacent) domains (Saraste and Svensson, 1991; Presley *et al.*, 1997; Scales *et al.*, 1997; Marra *et al.*, 2001). Two types of anterogradely moving IC elements can be resolved by LM, narrow tubules and large pleiomorphic structures. Some of the latter appear to represent saccular elements that transform into elongated structures ('thick tubules') (Presley *et al.*, 2002; Marie *et al.*, 2009). In addition, narrow tubules establish dynamic connections between the globular IC domains (Ben-Takaya *et al.*, 2005; Sannerud *et al.*, 2006).

Association with the Cytoskeleton

The long distance movements of the IC elements depend on MTs (Murshid and Presley, 2004; Palmer *et al.*, 2005; Figures 3

Figure 4 Immunoperoxidase EM analysis of the ultrastructure of p58-containing IC elements in NRK (a; inset) and mouse myeloma (b–f) cells. The protein is present in the *cis*-most Golgi cisterna (a) and in vesicular (arrowheads; ca. 80 nm in diameter), tubular (arrows) and saccular (asterisks; up to 0.5 μ m in diameter) IC elements. Panels (a–c) adapted from Ying, M., Flatmark, T., Saraste, J., 2000. The p58-positive pre-Golgi intermediates consist of distinct subpopulations of particles that show differential binding of COPI and COPII coats and contain vacuolar H^+ -ATPase. *Journal of Cell Science* 113, 3623–3638; (f) from Saraste, J., Palade, G.E., Farquhar, M.G., 1987. Antibodies to rat pancreas Golgi subfractions: Identification of a 58 kDa *cis*-Golgi protein. *Journal of Cell Biology* 105, 2021–2029. Nu; nucleus. Bars: 0.5 μ m (a–c), 0.25 μ m (d–f).

(b) and 6). The plus- and minus-end directed motor proteins kinesin and dynein associate with the IC elements (Lippincott-Schwartz *et al.*, 1995; Roghi and Allan, 1999; Stauber *et al.*, 2006), explaining their bidirectional movements even along the same MT tracks (Sannerud *et al.*, 2006). When the MTs in mammalian cells are depolymerized by nocodazole the IC elements become immobile and accumulate close to ERES (Saraste and Svensson, 1991; Hammond and Glick, 2000; Ben-Tekaya *et al.*, 2005; Sannerud *et al.*, 2006). Although the central Golgi ribbon breaks down, the formation of Golgi ministacks in the vicinity of ERES re-establishes ER–Golgi communication as a short range process (as in plants), explaining the ongoing Golgi modification and secretion of proteins (Saraste and Svensson, 1991; Cole *et al.*, 1996; Storrie *et al.*, 1998).

The Rho family GTPase cdc42, which regulates actin dynamics, interacts with COPI coats and affects dynein function, suggesting functional coupling between the actin filament system and MT-dependent motility of IC/*cis*-Golgi carriers (Luna *et al.*, 2002; Chen *et al.*, 2005). Similarly, WHAMM, which promotes actin nucleation and interacts with MTs, has been localized to the IC and implicated in the

formation and transport of pre-Golgi tubules (Campellone *et al.*, 2008).

Different IC Models

Transport Complexes

Based on imaging of fluorescent cargo, such as the VSV G-protein and procollagen, in living cells (Presley *et al.*, 1997; Scales *et al.*, 1997; Stephens and Pepperkok, 2002), it has been proposed that the IC represents a collection of large, pleiomorphic transport complexes (TCs) (Bannykh and Balch, 1997; Stephens and Pepperkok, 2001), which form via homotypic fusion of COPII vesicles, or protrude directly from the ER (Mironov *et al.*, 2003; Xu and Hay, 2004; Yu *et al.*, 2006). Thereafter, they move in a MT- and dynein-dependent (Burkhardt *et al.*, 1997) ‘stop-and-go’ fashion to the Golgi region, where they either fuse with or transform into *cis*-Golgi cisternae (Figure 7(a)). In other words, the IC elements are transient structures which are first formed *de novo* at ERES and then consumed at *cis*-Golgi. These mobile structures (speed of

Figure 5 Immunofluorescence LM localization of Rab1 in differentiating PC12 cells, illustrating the interconnected globular (arrowheads) and tubular (arrows) domains of the IC. Two confocal sections of the same cell are shown. The IC has expanded in response to a 24 h treatment with the nerve growth factor (NGF) and the tubules are found both in the cell body and the neurite-like extensions (right panel). Nu, nucleus; Golgi, perinuclear Golgi region. Bar: 5 μ m.

Figure 6 Bidirectional movements of GFP-Rab1A-positive tubules in a living NRK cell. Selected confocal images from a movie obtained by time-lapse microscopy are shown. Tubules extending from the same relatively stationary globular IC element (black arrowhead) pinch off and move either in the direction of the cell's leading edge (upper panels; yellow arrowheads), or toward the Golgi indicated by an asterisk (lower panels; red arrowheads). The paths taken by the tubules are highlighted in the time projection on the right. Adapted from Sannerud, R., Marie, M., Nizak, C., *et al.*, 2006. Rab1 defines a novel pathway connecting the pre-Golgi intermediate compartment with the cell periphery. *Molecular Biology of the Cell* 17, 1514–1526.

about 1 μ m/sec) corresponding to saccules or more complex, pleiomorphic elements (Mironov *et al.*, 2003) appear to consist of subdomains enriched in antero- or retrograde cargo, or

COPI (Shima *et al.*, 1999; Stephens *et al.*, 2000). They have also been shown to contain other machinery proteins, such as p23/24, p58, VIP36, membrin and Rab1A (Blum *et al.*, 1999;

Figure 7 Three views of the IC. All models take into account the existence of two types of ERES in mammalian cells, peripheral and Golgi-adjacent. For simplicity, lateral communication between ERES-adjacent IC elements is not illustrated. (a) The IC elements form *de novo* at ERES (via homotypic fusion of COPII vesicles), giving rise to pleiomorphic transport complexes (TC) that move along MTs to the *cis*-Golgi region where they either transform into *cis*-Golgi cisternae (as shown here) or fuse with the stationary Golgi stacks. (b) The IC consists of stationary membrane clusters located close to ERES. In this case ER-to-Golgi trafficking involves two distinct transport steps, since the IC receives cargo from the ER via heterotypic fusion of COPII vesicles and forms special anterograde carriers (AC) that move along MTs to *cis*-Golgi. (c) The IC represents a stable interconnected network that is anchored both next to ERES and the centrosome. Bidirectional transport between these sites and between the central IC elements and the Golgi stacks involves vesicular, tubular or saccular carriers. ERES-IC communication via COPII vesicles occurs as in model b. COPI, COPII and clathrin coats are shown in gray, orange, and blue, respectively, and the centrosome in red.

Chao *et al.*, 1999; Dahm *et al.*, 2001; Sannerud *et al.*, 2006; Monetta *et al.*, 2007; Tomás *et al.*, 2010).

Stationary Compartment

Another model of the IC (Figure 7(b)) is largely based on the imaging of GFP-ERGIC-53 dynamics in living cells (Ben-Tekaya *et al.*, 2005). It proposes that the IC consists of stationary, long-lived membrane clusters, located close to the ERES, which communicate with the ER and Golgi via distinct transport carriers (Appenzeller-Herzog and Hauri, 2006). Thus, in a two-step transport process cargo is first transferred from ER to the IC via heterotypic fusion of COPII vesicles. The IC then generates novel (possibly COPI-coated) anterograde carriers (ACs) that move along MTs to the *cis*-Golgi. The recycling of GFP-ERGIC-53 to the ER evidently occurs mainly from the ERES-associated IC, since it was not detected in the ACs containing soluble, Golgi-destined cargo. The identification of a motif in the neuronal GABA transporter, that seems to be required for its exit from the IC, supports the stable nature of the IC (Farhan *et al.*, 2008).

Interconnected Membrane System

Visualization of IC dynamics using GFP-Rab1A showed that the pleiomorphic transport carriers arriving along MTs from the cell periphery do not move directly to *cis*-Golgi, but are targeted to the MTOC/centrosome that is normally positioned next to the Golgi ribbon. In cells displaying centrosome motility, for example, cells that are migrating or entering mitosis,

the centrosome-targeted membranes can be resolved as a separate compartment, called the pericentrosomal IC (pcIC), which is distinct from the *cis*-Golgi-adjacent IC domain (Marie *et al.*, 2009, 2012; Mochizuki *et al.*, 2013; Figure 3(a)). Live imaging further showed that the separated pcIC and the Golgi communicate via tubular and globular carriers. The pcIC contains its own pool of COPI coats, and mediates the BFA-induced, COPI-independent backflow of Golgi enzymes to the ER, suggesting that forward pcIC-to-Golgi transport depends on COPI coats, and thus is blocked by BFA (Marie *et al.*, 2009).

Both the peripheral IC elements and the pcIC persist upon Golgi disassembly by BFA and maintain their communication with via dynamic tubules (Marie *et al.*, 2009). Accordingly, the IC has been proposed to constitute a dynamic, but stable membrane network due to its anchoring next to the ERES and the centrosome (Saraste *et al.*, 2009; Figure 7(c)). This model is supported by studies of mitotic cells, showing that the IC persists despite Golgi breakdown and the rearrangement of the MTs, and maintains its spatial organization due to its ongoing association with the spindle MTs and the centrosomes at the spindle poles (Marie *et al.*, 2012; Figure 3(a)).

Functional Aspects

Sorting and Transport

In the endocytic pathway, soluble proteins and particles bound to lysosomes accumulate in the lumen of vacuolar endosomes, while many membrane proteins are sorted into narrow tubules for recycling to the PM. The observed major

concentration of soluble secretory proteins within the IC (Oprins *et al.*, 2001) could be explained by similar geometry-based sorting, namely, their exclusion from vesicles and tubules, which recycle lipids and membrane-bound proteins back to the ER (Martínez-Menárguez *et al.*, 1999). Membrane recycling is a major function of both the IC and endosomes in mammalian cells. Due to the similarity of the tubular domain of the IC with the endocytic recycling compartment (ERC), its 'mirror compartment' next to the centrosome, it has been designated as the biosynthetic recycling compartment (BRC; Saraste and Goud, 2007; Marie *et al.*, 2009).

Luminal conditions: Receptor-mediated retrieval of KDEL proteins from the IC requires that it is discontinuous with the ER and maintains special luminal conditions (Pelham, 1989). The finding of low pH-dependent binding of KDEL-ligands to their receptor *in vitro* suggested the existence of a pH gradient between the ER and *cis*-Golgi (Wilson *et al.*, 1993). The pH-sensitive interactions of the low density lipoprotein (LDL)-receptor-related protein (LRP) and procollagen with the chaperones RAP and Hsp47, respectively (Bu *et al.*, 1995; Satoh *et al.*, 1996), and partial co-localization of DAMP (a marker for acidic compartments) and p58/ERGIC-53 in central IC elements (Palokangas *et al.*, 1998), are in accordance with this idea. The pH of the ER and *cis*-Golgi has been estimated to be about 7.2 and 6.5–6.7, respectively (Paroutis *et al.*, 2004; Vavassori *et al.*, 2013).

Although the effect pH on the binding of mannose-containing cargo to p58/ERGIC-53/LMAN1 remains unclear, it appears that cargo release is caused by a drop in free calcium concentration between the ER and IC lumen (Appenzeller-Herzog *et al.*, 2004; Bentley *et al.*, 2010; Zheng *et al.*, 2013). On the other hand, the depletion of luminal calcium stores affects the morphology of the IC and the recycling of cargo receptors at the ER–Golgi boundary, and the IC has been reported to contain the calcium-ATPase SERCA, as well as the calcium-binding proteins BiP, GRP94, CR, and CALNUP (Ying *et al.*, 2002; Breuza *et al.*, 2004; Howe *et al.*, 2009; Bentley *et al.*, 2010), suggesting its role in intracellular calcium storage.

Role of COPI coats: There are at least three subtypes of COPI coats (Beck *et al.*, 2009), and four Arf GTPases that regulate their membrane binding (Popoff *et al.*, 2011). Three Arfs appear to act at the ER–Golgi boundary and two of these associate with membranes in a BFA-resistant manner (Volpicelli-Daley *et al.*, 2005; Chun *et al.*, 2008; Duijsings *et al.*, 2009; Ben-Tekaya *et al.*, 2010; Hamlin *et al.*, 2014), suggesting that different types of COPI vesicles mediate two-way trafficking at the level of the IC. The role of COPI in anterograde transport has been considered for some time (Hosobuchi *et al.*, 1992; Pepperkok *et al.*, 1993; Peter *et al.*, 1993; Orci *et al.*, 1997; Malsam *et al.*, 2005). In addition, although both p58/ERGIC-53 and KDEL-receptor employ COPI vesicles in their recycling, their transport itineraries differ (Tang *et al.*, 1995a; Marie *et al.*, 2009, 2012). In addition to acting in vesicle budding the COPI coats may form membrane domains (Presley *et al.*, 2002).

Golgi bypass: Besides mediating bidirectional ER–Golgi trafficking, the IC has been suggested to be involved in Golgi-independent pathway(s) (Marie *et al.*, 2008; Saraste *et al.*, 2009). The route between the IC and the leading edge or growth cone of motile fibroblasts or neurons, respectively (Figures 5 and 6), could participate in cholesterol and integrin

trafficking (Urbani and Simoni, 1990; Sannerud *et al.*, 2006; Wang *et al.*, 2010) or correspond to the BFA-resistant ER-IC-PM route that supports phagocytosis (Becker *et al.*, 2005; Saraste and Goud, 2007; see below). Direct pericentrosomal communication between the IC and the endosomal system seems to be used by the cystic fibrosis transmembrane conductance regulator (CFTR) during its Golgi-independent transport to the cell surface (Yoo *et al.*, 2002; Marie *et al.*, 2009; Gee *et al.*, 2011). Further, the presence of the IC in neuronal dendrites may provide a Golgi-independent satellite pathway for local dendritic trafficking (Krijnse-Locker *et al.*, 1995; Sannerud *et al.*, 2006; Ehlers, 2013).

Posttranslational Modification

Questioning the studies on coronavirus maturation, which suggested that O-glycosylation is initiated in the IC (see above), subsequent EM studies showed that the GalNAc-transferases are predominantly found in the Golgi. However, the activation of cells (by epidermal growth factor) causes their incorporation into COPI vesicles and relocation to the IC and ER, which consequently become positive for the lectin Helix pomatia (Gill *et al.*, 2010). The cycling of *cis*-Golgi proteins to the IC could be a constitutive event (Lin *et al.*, 1999; Marra *et al.*, 2001; Jarvela and Linstead, 2012). Moreover, the construction of the sugar chains on proteoglycans has been suggested to begin in the IC (Jönsson *et al.*, 2003).

Protein Maturation

The KDEL-containing molecular chaperones present in the IC (BiP, PDI, and GRP94; see above) could be cycling while still bound to their unfolded client proteins, opening for a post-ER level of protein folding and quality control. The presence of quality control machinery in the IC and the finding that the ER-associated degradation of certain proteins requires their ER export is in accordance with this idea (Zuber *et al.*, 2001; Anelli and Sitia, 2008). The PDI family member Erp44 and p58/ERGIC-53 cooperate in the IC/*cis*-Golgi in sequential assembly of IgM polymers (Anelli and Sitia, 2008). Unassembled IgM or T-cell antigen receptor subunits bound to Erp44 or BiP, respectively, can be retrieved to the ER by the KDEL-receptor in a pH-dependent manner (Yamamoto *et al.*, 2001; Vavassori *et al.*, 2013), similarly as the overexpressed, misfolded VSV G-protein (Hammond and Helenius, 1994) and mutant V2 vasopressin receptors (Hermosilla *et al.*, 2004). Additional proof for a post-ER checkpoint is provided by studies showing the accumulation of the deletion mutant Δ F508 of CFTR (Gilbert *et al.*, 1998), misfolded MHC class I proteins (Hsu *et al.*, 1991; Raposo *et al.*, 1995), and proinsulin (Zuber *et al.*, 2004) in expanded IC elements.

Signaling

The level of p58/ERGIC-53 mRNA is up-regulated by the unfolded protein response (UPR), which also requires yeast Ypt1 function, supporting a link between this signaling pathway and ER–Golgi trafficking (Nyfeler *et al.*, 2003; Tsvetanova *et al.*, 2012). Protein kinases Src, aPKC, and Scyl1 have been

implicated in COPI function at the level of the IC (Tisdale and Artalejo, 2006; Hamlin *et al.*, 2014) and PKC and its downstream effectors appear to control IC morphology (Ben-Tekaya *et al.*, 2010; Sugawara *et al.*, 2012). The activation of neuronal Trk receptor tyrosine kinases in the IC initiates signaling via the MEK pathway leading to Golgi fragmentation (Scheeterson *et al.*, 2010).

Autophagy

Membranes enriched in IC markers (p58/ERGIC-53/LMAN1, KDEL-receptor, and Sec22B) play a role in the biogenesis of autophagosomes by representing the primary membrane source for the lipidation of LC3, which triggers this process (Ge *et al.*, 2013). Moreover, Ypt1/Rab1 is a key regulator of autophagy in yeast and mammals (Lynch-Day *et al.*, 2010; Winslow *et al.*, 2010; Zoppino *et al.*, 2010; Huang *et al.*, 2011; Lipatova *et al.*, 2012). A phosphatidylinositol 3-phosphatase (MTMR6) acting in vesicle transport and autophagy is regulated by Rab1B and localizes predominantly to the pIC (Mochizuki *et al.*, 2013), further supporting the role of the IC in autophagy.

Phagocytosis and Antigen Presentation

Supporting the existence of an unconventional pathway that connects the ER with the PM-derived phagosome (Gagnon *et al.*, 2002), the IC-enriched SNARE Sec22B/ERS-24 (Zhang *et al.*, 1999) was shown to influence phagocytosis independently of its role in ER–Golgi trafficking (Becker *et al.*, 2005; Hatsuzawa *et al.*, 2009). In dendritic cells the delivery of certain proteins – such as the peptide transporter (TAP), CR and tapasin – from ER to the phagosome is required for antigen cross-presentation. This pathway depends on the interaction between Sec22B and the PM SNARE syntaxin 4 and involves efficient recruitment of the integral IC components sec22B and p58/ERGIC-53 to the phagosomes (Cebrian *et al.*, 2011), in accordance with the idea that the IC provides an important membrane source for their formation. The presence of CR, tapasin, and functional TAP in the IC/cis-Golgi support this possibility (Kleijmeer *et al.*, 1992; Howe *et al.*, 2009; Ghanem *et al.*, 2010).

Links to Disease

The IC plays a role in the Golgi-independent trafficking of CFTR (see above). Mutations in p58/ERGIC-53/LMAN1, or its partner MCFD2 (multiple coagulation factor deficiency protein 2) result in an autosomal recessive bleeding disorder called combined deficiency of coagulation factors V and VIII. They disrupt the lectin mannose-binding protein 1 (LMAN1)-MCFD2 receptor complex, thereby inhibiting the secretion of these factors and reducing their serum levels (Nichols *et al.*, 1998; Zheng and Zhang, 2013). Parkinson's disease-related cytotoxic protein, α -synuclein, has been suggested to interfere with ER–Golgi trafficking and to arrest autophagy by inhibiting Rab1 function (Cooper *et al.*, 2006; Winslow *et al.*, 2010). Many phagocytosed bacterial pathogens, such as

Legionella, hijack the ER-to-IC-to-phagosome pathway during their intracellular replication (Isberg *et al.*, 2009; Arasaki *et al.*, 2012; see above). In addition to coronaviruses, the IC has been implicated in the replication of bunya-, entero-, flavi-, picorna, and vacciniaviruses (Jääntti *et al.*, 1997; Risco *et al.*, 2002; Miller and Krijnse-Locker, 2008; Hsu *et al.*, 2010). Surprisingly, p58/ERGIC-53 interacts in a lectin-independent manner with fusion proteins of a number of membrane viruses and participates in different stages of their life cycle (Klaus *et al.*, 2013).

The Golgi Apparatus – An Introduction

The Golgi apparatus and the closely associated *trans*-Golgi network (TGN) are the central transport stations of the eukaryotic secretory pathway, a fundamental positioning system through which a large fraction of the eukaryotic proteins (roughly 30% in mammals) are biochemically processed and conveyed from the site of synthesis, the endoplasmic reticulum (ER), toward their cellular destinations. The secretory pathway is, together with the endocytic apparatus, a major cellular organizer responsible for the location of every transported protein to the right cellular membrane or to the extracellular space, where these proteins must operate, as required for cell functionality.

Secretory traffic begins at the ER where cargo proteins are synthesized and inserted into the lumen or the membrane of this organelle. Cargo is then transferred, via the intermediate compartment (Appenzeller-Herzog and Hauri, 2006; Saraste and Kuismanen, 1992), to the Golgi complex, morphologically a stack of flat membranous cisternae enriched in glycosylating enzymes, and then through the *cis*-, *medial*- and *trans*-Golgi cisternae to the TGN, where it is sorted into membranous carriers for delivery to successive cellular destinations (De Matteis and Luini, 2008; Gu *et al.*, 2001). Along the way, and especially in the Golgi stack, cargo proteins (and lipids) are biochemically modified by glycosylation, the most abundant and complex eukaryotic posttranslational modification (Stanley, 2011); or they are broken down by degradative systems located in the ER (Vembar and Brodsky, 2008) and in the lysosomes (Luzio *et al.*, 2007). Moreover, at each transport stage, anterograde transport is balanced by regulated retrograde compensatory fluxes of membrane and proteins to maintain the morphological and compositional homeostasis of the system (Cancino *et al.*, 2014; Lorente-Rodriguez and Barlowe, 2011; Luini *et al.*, 2014). To carry out this enormous task, the transport apparatus relies on underlying molecular machinery that is estimated to comprise more than 2000 proteins, several hundreds of which reside in the Golgi/TGN (Gannon *et al.*, 2011; Gilchrist *et al.*, 2006).

The following description refers mostly to the mammalian Golgi complex, which has been extensively studied. The Golgi, however, is evolutionarily very ancient, most probably as ancient as the last common eukaryotic ancestor (LCEA), which appeared roughly 1.5 billion years ago (Klute *et al.*, 2011). Throughout evolution, the Golgi has varied significantly, especially in morphology, although its main functions, namely, glycosylation and transport and sorting, are likely to have been substantially preserved (Klute *et al.*, 2011).

The Structure of the Golgi Apparatus

The mammalian Golgi apparatus consists of hundreds of Golgi stacks that are typically made up of 3–6 flat cisternae of

about 1 μm in diameter (Klumperman, 2011; Figure 1). Cisternae are swollen at the rims, where transport takes place, and are decorated with perforations in the periphery, which may align across successive cisternae to form ‘wells’ (Rambourg and Clermont, 1990). Each Golgi stack is surrounded by numerous transport vesicles roughly 50–70 nm in diameter. The vesicles are especially concentrated near the rims and inside the wells (Ladinsky *et al.*, 1994). The Golgi stacks are linked together side by side to form a ribbon that is localized near the centrosome of the cell, by virtue of microtubule-based motors (Yadav and Linstedt, 2011). The links between stacks are constituted of tubules and perforated membrane areas (‘non-compact zones’) that typically join cisternae at the same level (i.e., *cis*-cisternae with *cis* and *medial* with *medial*) (Clermont *et al.*, 1994; Klumperman, 2011). In addition, connections may sometimes join different levels in adjacent stacks (Clermont *et al.*, 1994; Trucco *et al.*, 2004; Vivero-Salmeron *et al.*, 2008). These ‘heterologous’ connections, albeit infrequent, might be functionally important for transport through the Golgi stack (Beznoussenko *et al.*, 2014; Trucco *et al.*, 2004).

The *trans*-most and sometimes the penultimate cisternae extend tubules to form an interconnected tubular network at the *trans*-Golgi face, called *Trans*-Golgi Network or TGN (Gu *et al.*, 2001; Ladinsky *et al.*, 1994). The size of the TGN varies greatly with the secretory flux (Klumperman, 2011) and with transport conditions (Griffiths *et al.*, 1989). Sometimes, the *trans*-most cisterna can be seen to be ‘peeling off’ from the rest of the stack, again possibly as part of the transport process (Ladinsky *et al.*, 1994; Mogelsvang *et al.*, 2003; Rambourg and Clermont, 1990). Notably, though the TGN is a well-developed structure closely associated with the Golgi stack in mammalian cells, it appears to be an independent organelle in plants. The plant TGN receives endocytosed material from the plasma membrane, and acts as an early endosome. Indeed, TGN and early endosomes are generally considered a single organelle in plants, and distinctions, if any, between them have not been explored (Richter *et al.*, 2009). These and other observations (Lippincott-Schwartz *et al.*, 1991) suggest that the TGN might have evolved from endosomes early in evolution.

Transport through the Golgi

The Golgi is an obligate intracellular station for most of the secreted cargoes that move from the ER to other intracellular destinations. An exception is represented by a few cargo molecules that appear to bypass the entire secretory route and to follow an unconventional secretory pathway (Malhotra, 2013; Rabouille *et al.*, 2012). In the conventional route, secretory cargoes leave the ER via exit sites and reach the intermediate compartment before being transported to the Golgi via pleomorphic carriers (Appenzeller-Herzog and Hauri, 2006; Barlowe and Miller, 2013). The arrival at

the Golgi of cargo-laden carriers stimulates a compensatory retrograde transport from the Golgi to the ER that maintains membrane homeostasis at the Golgi (Cancino *et al.*, 2014; Lorente-Rodriguez and Barlowe, 2011; Luini *et al.*, 2014).

The cargo is then transported to the *trans*-Golgi side. The mode of transport through the Golgi has been studied intensely since the birth of cell biology roughly 50 years ago (Farquhar and Palade, 1998). Despite major advances, definitive conclusions have not yet been reached, mostly because of the enormous technical difficulty of imaging dynamic transport events within the compact Golgi stack with sufficient resolution in time and space. Historically, the dominant concept until the mid-1980s had been that traffic is mediated by vesicles shuttling between stable cisternae. This 'vesicular' model was based essentially on classical electron microscopy as well as on genetic and biochemical evidence (Palade, 1975; Rothman and Wieland, 1996; Schekman and Orci, 1996). The successive advent of more sophisticated imaging technologies stimulated a reexamination of the traffic mechanisms resulting in the proposal of the cisternal maturation model (Bonfanti *et al.*, 1998; Losev *et al.*, 2006; Matsuura-Tokita *et al.*, 2006). This scheme proposes that the cargo remains always in the cisternal lumen and the cisternae progress from *cis* to *trans* positions in the stack while 'resident'

components (e.g., glycosylation enzymes) move backwards in the *trans* to *cis* direction in lockstep with cisternal progression. Today, both models are still being considered, though the present evidence favors the cisternal maturation model. They are concisely presented below (see Glick and Luini, 2011; Figure 2).

According to cisternal maturation, cargo-containing carriers arriving from the intermediate compartment fuse together and align with the *cis*-Golgi face. The Golgi resident proteins are then retrogradely transported into the newly arrived membrane to create a new *cis*-cisterna. Cargo proteins remain inside this cisterna and move forward in the *cis* to *trans* direction. Once arrived at the *trans* position, the cargo-laden cisterna disassembles into transport carriers. At the same time, resident proteins (mostly glycosylation enzymes) shift backward in synchrony with cargo progression (Papanikou and Glick, 2014), maintaining the compositional gradient of the stack. This retrograde transport of enzymes has been proposed to be mediated by the vesicles present in the periphery of the stack and also by intercisternal continuities (Lanoix *et al.*, 2001; Martinez-Menarguez *et al.*, 2001; Rizzo *et al.*, 2013; Trucco *et al.*, 2004). This model is supported by the observation that macromolecular cargoes such as procollagen in mammalian cells (Bonfanti *et al.*, 1998) or scales in certain algae

Figure 2 Models of intra-Golgi transport. The cisternal maturation model proposes that the cargo is stably retained in the cisterna while the residents are transported retrogradely by COPI derived vesicles or intercisternal continuities. The vesicular transport model proposes that the residents are stably retained in the cisterna while the cargo is transported in the anterograde direction by COPI derived vesicles. See text for a more detailed description of these models and for a list of variants of these basic schemes. Reprinted with permission from Glick, B.S., Luini, A., 2011. Models for Golgi traffic: A critical assessment. Cold Spring Harbor Perspectives in Biology 3, a005215. Copyright Cold Spring Harbor Laboratory Press.

(Becker *et al.*, 1995) move efficiently through the stack despite being too large to enter the vesicles and while remaining always inside the lumen of cisternae (Bonfanti *et al.*, 1998); and by direct visualization of Golgi components moving backwards from distal to proximal cisternae, in synchrony with cisternal progression. This observation was made in *Saccharomyces cerevisiae*, where the cisterna are unstacked, allowing for better microscopic resolution (Losev *et al.*, 2006; Matsuura-Tokita *et al.*, 2006).

The vesicular transport model instead proposes that cisternae are stable and the resident enzymes remain permanently in their lumen, while the cargo traverses the stack in vesicular carriers. This scheme was proposed by Palade and colleagues (Palade, 1975) and substantiated by the *in vitro* studies of Rothman and colleagues, who identified the molecular machinery of transport and proposed that the features of such machinery are consistent with vesicular transport (Rothman, 2002). Yeast genetic studies conducted in parallel by Schekman and colleagues reached the same conclusions (Schekman, 2002). The main evidence in support of this model is that cargo can be visualized by super-resolution microscopy inside transport vesicles, at least under certain transport conditions (Jamieson and Palade, 1967; Malhotra *et al.*, 1989; Pellett *et al.*, 2013). In addition, several variants of this stable cisternae model have been proposed and are in consideration. These include the rapid mixing-partitioning model (Patterson *et al.*, 2008), the cisternal progenitor model (Pfeffer, 2010), the kiss-and-run transport model (Beznoussenko and Mironov, 2002), and the rimmel maturation model (Lavieu *et al.*, 2013). Finally, recent studies on the transport of soluble cargoes across the cisterna have shown that this type of secretory cargoes can diffuse across the stack via inter-cisternal continuities while other cargoes like procollagen move by cisternal maturation (Beznoussenko *et al.*, 2014). Altogether, the available data suggest that multiple mechanisms of transport may coexist in the Golgi stack.

The cargoes arriving at the TGN are transported to multiple destinations including the basolateral domain, apical domain, endosomes, ER, and the Golgi stack itself (Anitei and Hoflack, 2011; De Matteis and Luini, 2008). The first step in the transport of cargoes to their appropriate destinations is their sorting into cargo domains at the TGN from where they depart. The segregation of these domains is due in most cases on sorting signals present on the cargo proteins that bind to appropriate adaptors leading to their concentration and segregation (Bonifacino, 2014), although other mechanisms have also been demonstrated (De Matteis and Luini, 2008). This step is followed by the formation of cargo-laden transport carriers. Irrespective of their destination, most carriers that transport cargo out of the TGN are large pleomorphic structures (Polishchuk *et al.*, 2000, 2006). They form by the extrusion of the cargo domains along cytoskeletal tracks by motor proteins. The tubules connecting the carriers to the TGN are then severed to release the carriers that follow their course to their appropriate destination using cytoskeletal tracks (Luini *et al.*, 2008).

In addition to playing a role in the sorting of cargoes out of the Golgi, TGN also acts as recipient for incoming traffic from the endosomes that allow for the recycling of receptors such as M6PR (Pfeffer, 2011).

Molecular Mechanism of Transport

Membrane traffic in eukaryotic cells uses a 'toolbox' of molecular processes that are involved in the transport of cargo from one compartment to another (De Matteis and Luini, 2011; Figure 3). These 'elementary' processes include cargo sorting and membrane bending and budding mediated by 'coat' proteins, targeting of carrier vesicles to the target membrane by Rab and tethering proteins, and finally membrane fusion mediated by soluble NSF attachment receptors (SNAREs), where NSF stands for N-ethylmaleimide sensitive fusion proteins. Each of these processes is mediated by a class of machinery proteins specialized for each of these 'elementary' events such as fission, fusion, etc. Here, we briefly mention the Golgi-specific variants of the proteins involved in these processes, thus supporting transport across the stack. The members of these families of proteins that act at the Golgi include the COPI coat involved in cargo sorting and carrier formation (Popoff *et al.*, 2011), adaptors for the coat formation like GOLPH3 in COPI vesicle formation (Banfield, 2011) and AP-1 in clathrin-mediated vesicle formation (Bonifacino, 2014), phospholipase D2 involved in vesicle scission (Hsu and Yang, 2009), the COG family of membrane tethers (Willett *et al.*, 2013) and SNARE proteins membrin, syntaxin 5, GOS 28 etc. (Malsam and Sollner, 2011) involved in vesicle fusion. In addition, the Golgi matrix proteins (Munro, 2011) maintain the architecture of the Golgi and are also involved in vesicle tethering (Shorter and Warren, 2002).

Glycosylation at the Golgi

The proteins and lipids passing through the Golgi are processed by the Golgi-localized enzymes. The Golgi-localized glycan-modifying enzymes are type II membrane proteins with a short cytoplasmic tail and the catalytic portion of the enzyme localized in the lumen of the organelle (Hirschberg and Snider, 1987; Rini *et al.*, 2009). Usually, the localization of the enzymes reflects their order of action in the glycosylation pathway, with the early acting enzymes present in the *cis*-side of the Golgi and the later acting enzymes in the *trans*-side (Dunphy and Rothman, 1985).

The Golgi glycosylation enzymes are involved in the processing of N-glycans, O-glycan biosynthesis, proteoglycan biosynthesis, and glycolipid biosynthesis. The protein N-glycosylation starts with the transfer of precursor polysaccharides *en bloc* to a conserved Asn residue of the protein by oligosaccharyltransferase in the ER. The mannose residues are then trimmed in the ER before reaching the *cis*-Golgi where α -mannosidases further trim the glycan. This glycan then becomes the substrate for *medial*-Golgi localized N-acetylglucosaminyl transferase that transfers a N-acetylglucosamine residue onto the N-glycan. The product of these reactions becomes the substrate for galactosyltransferases and sialyltransferases in the *trans*-Golgi/TGN, thus leading to the formation of complex N-glycan (for further details see Stanley *et al.*, 2009). In contrast to N-glycosylation, O-glycosylation starts in the Golgi with the addition of N-acetylgalactosamine on serine/threonine residue of the proteins by galactosamine transferases. The galactosamine residue is further modified in the *trans*-Golgi/TGN to

Figure 3 A schematic representation of the ‘toolbox’ of processes used in the intracellular transport. The vesicle formation involves cargo sorting followed by membrane bending initiated by coat proteins. (a) The mature vesicle is then scissioned by dedicated factors. (b) The vesicle then translocates via microtubule-based motors to the appropriate target compartment (c), where it is tethered by a Rab and a molecular tether-dependent process (d) that also regulates the specificity of this vesicle tethering followed by docking through specific SNAREs. (d) SNARE pairing results in membrane fusion (e) delivering the cargo to the target compartment. A specific temporal combination of these elementary processes is used in all the transport pathways and see text for the Golgi-specific molecules involved in these processes at the Golgi apparatus. Copyright 2014, Massachusetts Medical Society.

create complex O-glycan forms (Brockhausen *et al.*, 2009). Similar to O-glycosylation, proteoglycan synthesis starts with the addition of a monosaccharide, namely xylose, to the

serine/threonine residue. That is then extended to a tetrasaccharide containing one xylose, two galactoses, and a single glucuronic acid residue. This tetrasaccharide is then extended depending on the type of proteoglycan to be synthesized. The glycan residues can also get other modifications such as sulfation as in the case of proteoglycans (Esko *et al.*, 2009) or phosphorylation as in the case of mannose-6-phosphate synthesis.

Glycolipid biosynthesis starts in the ER with the production of ceramide (Schnaar *et al.*, 2009). A peculiar feature of the lipid biosynthesis is the use of lipid transfer proteins that transfer lipids to the TGN where most of the glycolipid biosynthesis takes place. The ceramide produced in the ER is transferred by CERT (ceramide transfer protein) to the TGN where it is converted into sphingomyelin by the action of sphingomyelin synthases 1 and 2 (Hanada *et al.*, 2009). The rest of the ceramide is transported to the *cis*-Golgi where it is first converted into glucosylceramide by glucosylceramide synthase and then processed in the TGN to produce complex glycosphingolipids (D’Angelo *et al.*, 2013).

The sugar residues needed for glycosylation reactions are transported into the lumen as nucleotide sugar units by transporters. While sialic acid is imported as CMP-sialic acid and fucose as GDP-fucose, most other sugars are imported as UDP-sugar conjugates (for further details, see Freeze and Elbein, 2009). The vacuolar-ATPase localized to the *trans*-side maintains an acidic pH required for the glycosylation reactions and the neutralization of pH impairs glycosylation (Rivinoja *et al.*, 2012).

Regulation of the Golgi Apparatus Structure and Function

Given the complex structural and functional features of the Golgi, it is not surprising that these features are controlled by specialized regulatory mechanisms. Screening studies have shown that the secretory pathway is under the regulation of many kinases and phosphatases (Chia *et al.*, 2012; Farhan *et al.*, 2010; Simpson *et al.*, 2012; Zacharogianni *et al.*, 2011). Here we highlight a few such processes where the significance of this kinase-mediated regulation is understood.

Some of these processes are involved in the maintenance of the homeostasis of the transport apparatus. Transport involves large membrane and protein fluxes across the transport stations, that are subjected to physiological and pathological perturbations as well as to spontaneous drifts away from equilibrium (Hirschberg *et al.*, 1998; Mironov *et al.*, 2001; Pulvirenti *et al.*, 2008; Trucco *et al.*, 2004). Such perturbations can be a serious threat to the homeostasis, as they might alter the composition and morphology of the transport compartments disrupting their function. An example of this possibility is transport at the interface between ER and the Golgi complex. The ER is roughly 10-fold that of the Golgi in size (Griffiths *et al.*, 1984) and, its membrane output toward the Golgi can represent a significant fraction of the Golgi volume/surface (Griffiths *et al.*, 1984; Klumperman, 2000; Martinez-Menarguez *et al.*, 1999; Thor *et al.*, 2009). Thus, even minor changes in export from the ER would cause major alterations in Golgi morphology and composition, if not compensated for by

corresponding changes in retrograde transport from the Golgi to the ER (Klumperman, 2000; Martinez-Menarguez *et al.*, 1999; Thor *et al.*, 2009). However, the Golgi always maintains or recovers its normal composition and morphology (Mironov *et al.*, 2001; Trucco *et al.*, 2004). At least some of the underlying compensatory mechanisms use control devices that sense the changes/perturbations and respond quickly, precisely, and appropriately to restore homeostasis.

One regulatory device that operates at the interface between ER and Golgi has been investigated fairly extensively, and concepts on the molecular composition and design of these devices have begun to emerge (Cancino *et al.*, 2014). Membrane fluxes leaving the ER for the Golgi result in the activation of a traffic sensor, or receptor (the KDEL), at the *cis*-Golgi. This acts as a signaling protein that activates transduction pathways that are similar in composition to canonical PM signaling pathways and kinase cascades. These kinases phosphorylate a large number of Golgi and cytosolic proteins, some of which are involved in anterograde and retrograde traffic. As a result, anterograde and retrograde traffic become activated, counteracting the accumulation of membrane/proteins that would result from a non-compensated continuous arrival of traffic to the Golgi and hence helping to maintain Golgi homeostasis. Whether this scheme applies at other stages of the trafficking pathways remains to be investigated.

Simpler molecular processes involved in the transport are also subjected to regulation. One particularly clear example is the regulation of uncoating of COPII-coated carriers. The COPII-coated carriers derived from the ER fuse with the Golgi apparatus to deliver the cargo and the regulation of uncoating of the carrier only at the appropriate compartment (Golgi) prevents the possibility of engagement with an inappropriate compartment. This is accomplished by the specific localization of casein kinase 1d at the Golgi that can phosphorylate the COPII coat components upon arrival of the anterograde carrier at the Golgi, leading to its uncoating and subsequent fusion with the Golgi cisternae (Lord *et al.*, 2011). Finally, the glycosylation processes at the Golgi are also subjected to regulation. Examples include the Src kinase-mediated regulation of the localization of N-acetylglucosamine transferases that initiate o-glycosylation (Chia *et al.*, 2012; Gill *et al.*, 2010) and the regulation of import of N-acetylgalactosamine into the Golgi lumen that determines branching of N-glycans (Lau *et al.*, 2007).

Role of Golgi in Disease

Given the central role played by the Golgi apparatus in the processing and secretion of proteins, a defect in Golgi function results in serious disorders/diseases (for a detailed discussion see Freeze and Ng, 2011). The disorders affecting specific glycosylation pathways lead to similar symptoms. For example, defects in O-mannose biosynthetic pathways lead to diseases involving muscular dystrophy probably due to the high levels of O-mannose present in α -dystroglycan while defects in proteoglycan biosynthesis mainly causes skeletal disorders since extracellular matrix abundant in proteoglycans plays a major role in bone development (Freeze and Ng, 2011). Golgi-associated diseases also occur due to mutations in the genes encoding proteins that form part of the structural/mechanistic

processes of the Golgi. Since a defect in structural or mechanistic processes affect many aspects of Golgi function, the disorders result in a plethora of symptoms. A classic example of such disorders is the congenital glycosylation disorders (CGD) caused due to mutations affecting the COG subunits involved in the recycling of Golgi residents, a process required for their appropriate localization (Zeevaert *et al.*, 2008). CDG disorders involving almost all the subunits of COG complex have been documented and the patients with these disorders show symptoms of impaired development, mental retardation, and hypotonia in many cases along with other subunit-specific symptoms (Freeze and Ng, 2011). In addition, mutations in a subunit of V-ATPase that is required for the maintenance of the pH inside the Golgi lumen essential for glycosylation result in connective tissue disorders with wrinkly skin (Cutis laxa) (Rosnoblet *et al.*, 2013).

Apart from the genetic diseases mentioned above, Golgi proteins have also been linked with various other diseases including cancer, infection, etc. (Hu *et al.*, 2007; Varki and Freeze, 2009; Varki *et al.*, 2009b). For instance, the Golgi-localized protein GOLPH3 has been recently shown to be overexpressed in solid tumors and to act as an oncogene (Scott *et al.*, 2009).

Evolution of the Golgi Apparatus

The secretory pathway is a central component of the eukaryotic endomembrane system and the Golgi apparatus plays an essential role in it. Nevertheless, and rather surprisingly, there are organisms that do not seem to have a recognizable Golgi apparatus and that led to the suggestion these organisms might represent the earliest branches of the eukaryotic tree before the evolution of a functional Golgi apparatus (Cavalier-Smith, 1987). Later phylogenetic studies indicated that this was not the case (reviewed in Mowbrey and Dacks, 2009) and suggested that the Golgi apparatus is a universal feature of the eukaryotic cells and probably the LCEA did have a functional Golgi apparatus.

The Golgi apparatus varies in shape from a ribbon-like Golgi in mammalian cells to scattered stacks in the plants or insect cells to unstacked fragmented Golgi cisterna in *S.cerevisiae*. This led to the question about the nature of Golgi apparatus present in the LCEA. Phylogenetic studies have shown that organisms that lacked Golgi stacks are embedded in clades that had stacked Golgi apparatus suggesting that the absence of a stack in certain organisms could be a secondary loss and there were at least eight such independent instances of Golgi unstacking during the eukaryotic evolutionary history (Mowbrey and Dacks, 2009). In addition, a recent phylogenomic study has shown that almost all the categories of Golgi proteins including SNAREs, Rabs, and matrix proteins are conserved across all the eukaryotes with secondary losses seen in some branches (Klute *et al.*, 2011). Given the importance of matrix proteins in the stacking of the Golgi (Seemann *et al.*, 2000; Shorter and Warren, 2002), this supports the idea that early eukaryotes probably had a stacked Golgi.

Apart from this conserved properties, evolutionary innovations have played a part in modifying and adapting the Golgi to the need of the organisms. A clear example is the evolution of ribbon-like organization in the vertebrates (Wei and Seemann, 2010). This structure is also present in sea urchin (Terasaki,

2000), suggesting that probably it is a deuterostome innovation. Cell-biological studies have pointed to a role for the Golgi ribbon in the efficiency of glycosylation (Puthenveedu *et al.*, 2006; Xiang *et al.*, 2013) and transition to deuterostomes is accompanied by huge increase in the diversity of glycosylation products made by the Golgi apparatus with a pronounced increase in sialylated products (Varki *et al.*, 2009a). Thus, the formation of the ribbon-like Golgi apparatus may have accompanied or contributed to the evolution of deuterostomes.

Another innovation during the course of evolution was the development of the TGN. While the TGN is rudimentary in most organisms, it is a well-developed structure in the mammalian cells (probably also in other vertebrates). Moreover, in some organisms the TGN and endosomes are identical (e.g., in plants) (Richter *et al.*, 2009) while the mammalian TGN is distinct from the endosomes, with extensive membrane traffic between them. The expansion of the TGN and development of the ribbon-like structure was also accompanied by expansion in the repertoire of membrane traffic regulators with the human genome encoding nearly 30 known Rab proteins (Diekmann *et al.*, 2011). Whether the evolution of TGN also parallels an increase in the number of sorting pathways exiting the TGN and how this may have contributed to the evolution of mammals remain open questions.

Perspectives

After more than a century after its discovery, our understanding of the functioning of the Golgi apparatus remains uneven. While there is as yet no consensus on aspects as basic as the mode of intra-Golgi transport or a definitive list of TGN exit pathways, the genomic and proteomic studies have led to a rather extensive catalog of proteins localized to the Golgi apparatus and to a satisfactory understanding of the molecular processes they execute. The progress in addressing the unresolved issues is intimately connected with advances in imaging technology and with the use of novel reconstitution approaches (Wakana *et al.*, 2012). Some of these aspects, including glycosylation, regulation of Golgi homeostasis, and cell-type specific variations of Golgi structure/function are yet to be explored in detail. The resolution of these basic questions of transport along with advances in the analysis of functional aspects of the Golgi at a molecular level is necessary to build a satisfactory systems understanding of the Golgi apparatus.

Early Endosomal Compartments

Endosomes

A hallmark of eukaryotic cells is the compartmentization of their cytoplasm which allows for the parallel processing of biochemical reactions with different requirements for optimal execution. All eukaryotic cells have endosomes which constitute a pleiomorphic interconnected membrane system important for many basic cellular processes including nutrient supply, signaling, and plasma membrane protein regulation. In multicellular organisms these features contribute in an essential manner to cellular phenotypes as shape, migration, motility, and division and in doing so are of importance in developmental processes and tissue homeostasis.

Endosomes and their role in biology have been firmly established and incorporated in the textbooks. This fact on itself actually bears testimony to the enormous development in imaging technologies that allowed us to rapidly accumulate a wealth of information on an organelle whose existence was unknown in the late 1970s. At that time the lysosome, an acidic degradative organelle was considered to be the destination of all endocytosed molecules and solutes. Observations of Hubbard, Steinman and Cohn, and Goldstein and Brown indicated that the synthesis rate of endocytosed membrane lipid, cell surface proteins, and receptors was insufficient to maintain the surface area of a cell and steady state pools of the proteins they studied (Steinman *et al.*, 1983; Goldstein *et al.*, 1985). Accumulating evidence converged on the notion that salvage pathways had to exist for the return of endocytosed materials back to the cell surface. Early EM studies revealed the existence of prelysosomal vacuoles that were more electronlucent than the typical acid hydrolase containing lysosomes and which could serve as the locale for escape from lysosomal degradation (Helenius *et al.*, 1983). In kinetic experiments on the mechanism of Semliki Forest virus penetration in tissue culture cells Helenius discovered that the low pH-mediated fusion occurred prior to localization of virions in lysosomes, which demonstrated a function for the acidic prelysosomal structures. The subsequent discovery of ATP-driven acidification activity in endosomal membranes cemented the notion that endosomes share the ability with lysosomes to acidify their lumen albeit to a lesser extent (Mellman *et al.*, 1986).

Endosome Heterogeneity Reflects Functional Compartmentalization

Microscopy studies showed that some endocytosed molecules like epidermal growth factor and low-density lipoprotein moved centripetally from small peripheral cytoplasmic structures close to the cell surface to more centrally located larger multivesicular organelles and subsequently 'true' lysosomes.

Other tracers of which Transferrin (Tf) and its receptor (TfR) are the archetypical representatives accumulated transiently near the microtubule organizing center before disappearing from the cell without being degraded. Biochemical correlates were derived from internalization experiments followed by cell fractionation where endocytosed tracers initially appeared in a mildly acidic light membrane fraction ('early endosomes') and next in more acidic, heavier membranes ('late endosomes') with different but overlapping protein composition which stand apart from lysosomes in terms of enrichment profiles for markers and isolation by density gradient centrifugation (Schmid *et al.*, 1988). These and many other microscopy and fractionation studies of increasing sophistication established the paradigm that the term endosome actually encompasses a heterogeneous class of structures both in terms of morphology and function that endow the animal cell with the ability to sort a subset of endocytosed cargo molecules for recycling and re-utilization, while other cargo is dispatched to lysosomes and disposed of by degradation (Geuze *et al.*, 1984; Figure 1).

Recent studies have begun to describe the macroscopic properties of the early endosomal system as an ensemble of individual elements that continuously exchange content through fusion and fission. The system analysis approach lends credence to the notion that the net effect of vesicle interactions is the continuous merger into larger ones with increased cargo content (Foret *et al.*, 2012). Interestingly, the quantitative description follows the same mathematical principles as those that were originally derived for the assembly of colloidal particles in larger clusters.

Epithelial Cells Have Spatially Separated, Connected Endosomal Circuits

The organization of endocytic organelles and pathways in epithelial cells is more complicated. The polarized phenotype of these cells is a consequence of the interplay between a epithelial polarity establishing program, positional sensors, and a polarized trafficking machinery (Weisz and Rodriguez-Boulan, 2009; Datta *et al.*, 2011). Maintenance of the chemically distinct apical and basolateral domains is of utmost importance for the barrier function and performance of transport in this cell type. This is most dramatically testified in the rare genetic disease 'microvillus inclusion disease' where inactivating mutations in MYO-Vb cause abnormal development of the apical cell surface, mislocalization of apical protein, and severe diarrhea (Müller *et al.*, 2008).

Since endocytosis can occur from both apical and basolateral plasma membrane, epithelia essentially duplicated early endosomal compartments. Endocytosed molecules first meet basolateral or apical early endosomes (AEE) that both feed into apical recycling endosomes. From these spatially

Figure 1 Overview of generic endosomal compartments. Simplified schematic of the endosomal system and its internal connectivity. Molecules that enter early endosomes (EE) are sorted in two major exit routes that either bring them back to the cell surface directly or via recycling endosomes (RE). The other pathway leads via late endosomes/multivesicular bodies (LE/MVB) to lysosomes or retrieval to the trans Golgi network (TGN). The tubular RE system is sometimes localized in the perinuclear region through interaction with the microtubule organizing center (MTOC). The core endosomal rab GTPases associated with regulation of transport through the conduits are indicated and further described in the main text.

separated early endosomes, material is either returned or transcytosed (for basolaterally internalized molecules) to the apical cell surface, or transported to a common recycling endosome above the nucleus. The common recycling endosome is the sorting station for delivery of cargo to the basolateral plasma membrane or targeting to common lysosomes. Specific sorting signals in cargo molecules are recognized by cytoplasmic machinery for incorporation in apically or basolaterally targeted carriers equipped with the appropriate SNARE proteins for fusion with apical and basolateral domains, respectively (Weisz and Rodriguez-Boulan, 2009; Figure 2).

(Ultra)structure and Specialization

Early endosomes (EE) consist of a vacuolar part from which one or more tubules emanate (Geuze *et al.*, 1984). The vacuolar portion serves to sort proteins in the degradative pathway and is also known as sorting endosome, which matures through sequential and cooperative recruitment of rab5 and rab7 effector networks into late endosomes (Rink *et al.*, 2005). The acidic endosomal pH causes dissociation of many ligands and receptors whereupon soluble ligands end up

in the vacuolar portion of the endosome (Maxfield and McGraw, 2004). The tubules may detach from the vacuolar part and oftentimes form a network, known as recycling endosomes. These typically contain a transient pool of intracellular receptors that are targeted for recycling to the plasma membrane. In some cells the tubular network has a very characteristic location adjacent to the microtubule organizing center, presumably through interaction with (peri)centriolar proteins (Maxfield and McGraw, 2004). A third exit conduit is used to recycle a subset of endosomal cargo molecules to the trans Golgi network (Bonifacino and Rojas, 2006). Finally, specialized cells have evolved unique endosome exit pathways that are vital to perform their dedicated functions, an example of which is provided by the presynaptic neuron. To prevent depletion of synaptic vesicles during neuronal stimulation, the rapid exocytosis of neurotransmitter is followed by an ultrafast endocytic pathway for retrieval of synaptic vesicles which involves the formation of new synaptic vesicles from early endosomes (Watanabe *et al.*, 2014).

A major fraction of internalized cell surface protein is recycled back from early and recycling endosomes to the plasma membrane. Because the surface to volume ratio of a thin tubule is much larger than of a spherical vesicle or the vacuolar

Figure 2 Endosomal organization in polarized epithelial cells. Molecules can endocytosed from the apical and basolateral cell surfaces into AEE and basolateral early endosomes (BEE), respectively. A large fraction is recycled directly, or via common recycling endosomes (CRE) or apical recycling endosomes (ARE) to the cells surface from where they originate. Depending on the sorting information present in cargo molecules, some are sorted for transport into the degradative pathway to late endosomes (LE)/lysosomes (L). Other cargo is sorted from the CRE to the cell surface opposite from where they are internalized, a pathway also known as transcytosis. Newly synthesized molecules are sorted from the TGN to the basolateral surface or via the endosomal compartments to various destinations.

part of the endosome, principles of calculus readily explain a passive endosomal sorting activity that directs receptors in tubules and ligand in the vacuolar part. For a long time the geometry-base paradigm was the driving force for the notion that sorting in the recycling pathway occurred by default.

Endosomal export has similarities with the process that delivers molecules from the cell surface to early endosomes. Although we generally refer with the single terms endocytosis and recycling to each of them, they actually represent multiple routes that end in, or leave from endosomes, respectively. From a logistic point of view transport pathways can be considered and in fact serve as a means of intracellular communication. Communication within the endosomal system and with the distinct destinations is brought about by vesicular transport pathways of unforeseen and increasing complexity. Vesicle formation is initiated by recruitment of cytoplasmic coat complexes to specific regions of the membrane, selection of cargo molecules, and reshaping the marked membrane

regions into vesicles of defined size between 40 and 80 nm (Bonifacino and Glick, 2004).

Regulation of Endosome Traffic

The architectural integrity of the endosomal system depends on sophisticated control systems for coordinating the transport routes for entry and exit of the lipids and proteins needed for maintenance of organelle identity. Two classes of molecules namely small GTPases of the rab and ADP ribosylation factor/Arf-like (Arf/Arl) families, and phosphoinositides (PIs) are thought to provide compartment specific tags and serve as key regulators of traffic and homeostasis within the endosomal system (Jean and Kiger, 2012). Endosomal membranes can be populated by more than one rab protein and may also display lateral heterogeneity in terms of phosphoinositide species which allows for the coupling of cargo entry and exit from that

membrane region. Although each in its own right can regulate independent processes, the simultaneous presence and concerted activities of a specific rab, Arf/Arl, and phosphoinositide in a membrane region is likely essential to achieve the requisite fidelity in endosomal trafficking pathways.

Rab Proteins

The best understood endosome-associated rab proteins are rab4 (early endosomes-recycling endosomes), rab5 (plasma membrane-recycling endosomes), rab7 (late endosomes-lysosomes), rab9 (late endosomes), and rab11 (recycling endosomes). Rab GTPases are molecular switches that cycle between an active guanosine triphosphate (GTP)-bound and inactive guanosine diphosphate (GDP)-bound state. GTPase Activating Proteins (GAPs) accelerate the intrinsic hydrolysis rate, while guanine nucleotide exchange factors (GEFs) catalyze the conversion of the GDP to GTP state. While the GTP-form of rab proteins is bound to the cytosolic leaflet of the endosomal membrane, the GDP form resides in the cytoplasm in a complex with the chaperone rab-GDP dissociation inhibitor (rab-GDI) that shields the hydrophobic geranylgeranyl groups in the C-terminal hypervariable region. The rab-rabGDI complex is needed for initial and reversible delivery of rabs to membranes. The specificity of which is provided by signals within the cognate GEF and the rab-rabGDI complex. Elegant studies with mitochondria-targeted cognate GEFs established that rab GEFs serve as the minimal machinery for targeting and activation of rab proteins including endosomal rab5 and rab35 (Barr, 2013). The active form of rabs binds to specific effectors and thereby creates oligomeric protein complexes that form nanodomains within the endosomal membrane. The rab-effector complexes provide spatiotemporal control of an array of processes including those that regulate shape and location of endosomes via interactions with cytoskeleton and motor proteins, phosphoinositide metabolizing enzymes, tethering factors, fusion and fission regulators, and signaling molecules (Wandinger-Ness and Zerial, 2014).

Some of the rab effectors pair with several rab proteins whose activity is sequentially organized along the endocytic route. On early endosomes, the rab5 effectors rabenosyn-5, rabaptin, and rabip4's each interact with, and have separate binding domains for rab5 and rab4 while rab4 and rab11 are coupled through such effectors as D-AKAP-2 and GRASP-1 in neurons (Wandinger-Ness and Zerial, 2014).

Bivalent effectors of endosomal rab proteins provide an attractive model to spatially link cargo delivery by incoming transport vesicles in the rab5 domain with carriers leaving endosomes from the adjacent but overlapping rab4 domain (Wandinger-Ness and Zerial, 2014). Conceptually this scenario is related to the coupling of exocytosis and re-intake of synaptic vesicles in neurons, or secretory lysosomes at the immunological synapse in cytotoxic lymphocytes. Mechanistic details of the molecular processes supporting this model however need to be established first.

Phosphoinositides

The endosomal localization of phosphoinositides just like that of rab proteins is also controlled by members of two classes of

enzymes (Jean and Kiger, 2012). Specific lipid kinases and phosphatases catalyze the formation and consumption of a substrate phosphatidylinositol. Their relative activity or location thereby drives the reversible localization of a given phosphatidylinositol (PI) in a membrane or organelle. The principal endosomal phosphatidylinositol is phosphatidylinositol 3-phosphate (PI(3)P) that to a large extent is produced by the type III kinase Vps34 on endocytic vesicles, where it controls docking and subsequent fusion of early endosomes (Wandinger-Ness and Zerial, 2014). PI(3)P binds to proteins containing a PX (after p40phox and p47phox subunits of NADPH oxidase) or FYVE domain (acronym of Fab1, YOTB, Vac1, EEA1, the founding members of this protein family) and serves as cue for endosomal localization. Some of the FYVE proteins like early endosome antigen (EEA1), rabankyrin, and rabenosyn-5 also interact with active rab5, and the simultaneous binding to PI(3)P and rab5 ensures the specificity and avidity required for their endosomal localization (Wandinger-Ness and Zerial, 2014).

PI(3)P generated by Vps34 serves as a docking site for phosphatidylinositol 3-phosphate 5-kinase PIKfyve which converts PI(3)P into PI(3,5)P₂, whose effectors are involved in sorting to the multivesicular body (Odorizzi *et al.*, 1998). PI that is funneled through Vps34 is primarily involved in initial stages of multivesicular body formation through the localization of PI(3)P effector hepatocyte growth factor-regulated tyrosine kinase substrate (Hrs) to a atypical clathrin-coated region on the vacuolar part of early endosomes (Sachse *et al.*, 2002). The adaptor that links endocytic cargo to the endosomal sorting complex required for transport (ESCRT) coat is Hrs, whose ubiquitin interacting motifs interact with ubiquitinated endosomal cargo molecules tagged for degradation (Umebayashi *et al.*, 2008). Through interactions with signal transducing adaptor molecule (STAM), Hrs assembles into a poly ubiquitin binding platform named ESCRT-0, which constitutes the first stage of ESCRT complex assembly (Bache *et al.*, 2003). A newly identified role of this PI(3)P pool relates to a localization in cytokinetic bridges during mammalian cytokinesis for recruitment of the FYVE-CENT protein (Sagona *et al.*, 2010). Together with the motor kinesin family 13A (KIF13A) and tetratricopeptide repeat domain protein 19 (TTC19), FYVE-CENT is thought to cooperate with the charged multivesicular body protein 4 (CHMP4) subunit of ESCRT-III in abscission.

Exocytic pathways leaving early endosomes do not seem to be controlled by Vps34 but instead depend on phosphoinositide 3-kinase C2α (Falasca *et al.*, 2007), a kinase that is far less sensitive to classical inhibitors LY294002 and wortmannin. The question then becomes whether early endosomes contain independent pools of PI(3)P that are involved in different aspects of early endosome function as is the case with PI(4,5)P₂ on the plasma membrane. Several recent studies now start to shed light on this question and reveal that the early endosomal system harbors distinct PI(3)P pools. Phosphatidylinositol 3-phosphate kinase (PI3K) C2α not only resides on the plasma membrane but has been found in clathrin-coated vesicles as well and in perinuclear recycling endosomes. The recycling endosome PI(3)P pool generated by PI3K C2α activates rab11 and via a rab11-rabin8-rab8 cascade regulates the function of primary cilia (Franco *et al.*, 2014).

Coordination of Phosphoinositides and Rab Proteins

PI kinases and rab proteins coordinately regulate endosome dynamics via multiple mechanisms. Often these involve the enzymatic activity of the PI kinases as with rab5 and Vps34 in endosome maturation (cf. below). In other instances the PI kinase serves a structural role, not directly related to its enzymatic activity. The function of rab11 in exocytic pathways depends on the interaction with a member of the PI4 kinases namely PI4KIII β . The two proteins co-localize on recycling endosomes and the trans Golgi network and the function of rab11 critically relies on PI4KIII β (De Graaf *et al.*, 2004). The kinase directly binds rab11 and functionally recruits it to membrane via a novel mechanism that is both dependent and independent of the lipid kinase activity (De Graaf *et al.*, 2004). In fruit fly, rab11 and the downstream effector Nuclear Fallout (ortholog of the human rab11-FIP3 (rab11 family interacting protein 3)) depend on Four Wheel Drive (PI4KIII β) for membrane localization, a prerequisite for cytokinesis (Polevoy *et al.*, 2009). Membrane ingression at the end of the asexual erythrocytic stage in the *Plasmodium falciparum* life cycle similarly depends on rab11 and PI4KIII β (McNamara *et al.*, 2013). In the rab11-PI4KIII β -FIP3 complex structure (Burke *et al.*, 2014), PI4KIII β only makes a single peripheral contact with rab11 switch region I, while molecular interactions with switch region II are absent. As a consequence the rab11 switch regions remain available for simultaneous FIP3 binding and by inference interactions with other effectors. The requirement for PI4KIII β enzyme activity likely reflects the role of its product PI(4)P in the recruitment of a DENND4 (differentially expressed in normal and neoplastic cells 4) type rab11 exchange factor (Xiong *et al.*, 2012) to activate rab11 as for the orthologs Ypt32 (yeast protein 32) and Pik1 (yeast 1-phosphatidylinositol 4-kinase) in yeast.

Early Endosome Maturation and Conversion to Late Endosomes

Endocytic internalization and early to late endosome conversion and maturation are the best understood trafficking pathways in terms of the interdependence of rab proteins and PI regulators. Rab5 and rab7 both interact with Vps34 and stimulate its enzyme activity. The increased PI(3)P levels in the endosomal rab5 domain serves to recruit proteins with FYVE signature and rab5 binding regions (cf. above) through coincidence detection. PI3K β on the cell surface and clathrin-coated vesicles is also activated by rab5 binding and generates PI(3,4,5)P₃ from PI(4,5)P₂ at these locations. Through downstream rab5 interactions with polyphosphate 4-phosphatase and inositol polyphosphate 5-phosphatase, PI(3,4,5)P₃ is converted to PI(3,4)P₂ and PI(3)P, which in parallel to the PI3K C2 α pathway contributes to the formation of a gradient of PI3P from the plasma membrane to early endosomes (Wandinger-Ness and Zerial, 2014).

The PI(3)P molecules on early endosomes are turned over via several mechanisms. First, recruitment of PIKfyve converts PI(3)P to PI(3,5)P₂. A second pathway involves activation of rab7 which sequesters Rubicon, a negative regulator of UV radiation resistance-associated gene (UVRAG) that binds the

Vps34-p150-beclin1 core complex for fusion on early endosomes (Sun *et al.*, 2010). As a consequence UVRAG activates the homotypic vacuolar protein sorting complex (HOPS) complex, a rab7 effector tethering late endosomes for fusion. The PI conversion pathways are superimposed on a rab cascade where rab5 is replaced by rab7 (Rink *et al.*, 2005). The essentials of the latter include the disruption of the positive cooperativity in the rab5 pathway via which rabex-5-rabaptin-5 exchange factor complex contributes to recruitment of additional rab5 effector molecules. Key events in this partially elucidated pathway are docking of the rab7 exchange factor Mon1-Ccz1 (Nordmann *et al.*, 2010) on rab5 and PI(3)P and removal of the rab5 exchange factor. GTP hydrolysis of rab5-GTP will cause dissociation of rab5GDP (Poteryaev *et al.*, 2010), recruitment and activation of rab7 and the assembly of a late endosomal domain populated by rab7-GTP and its own effectors such as the HOPS complex, RILP (Rab7-interacting lysosomal protein) and dynein motors (Johansson *et al.*, 2007), and retromer (Rojas *et al.*, 2008).

Proteins that do not contain the signals for targeting and degradation in late endosomes/lysosomes are either retrieved to the trans Golgi network or recycled to the plasma membrane. The transport carriers that are used in both exit ways are formed from tubular extensions on early endosomes. In the following sections, these pathways will be discussed in more detail.

Retrieval of Proteins from Endosomes to the Trans Golgi Network

Early work by Seaman and Emr (Seaman *et al.*, 1998) led to the identification of retromer as a coat complex required for the return of Vps10, a trans Golgi network (TGN) sorting receptor for the vacuolar enzyme carboxypeptidase Y and counterpart of the mammalian Mannose 6-Phosphate Receptor. The subunits of yeast retromer are organized in two interacting subcomplexes consisting of Vps26-Vps35-Vps29 trimer and a Vps5-Vps17 heterodimer. The first of which is highly conserved, interacts with cargo (Notwehr *et al.*, 2000) and is known as cargo selection complex, while Vps5 and Vps7 are member of the sorting nexin (SNX) family with more sequence diversity. Vps5 and Vps7 contain BAR (Bin-Amphiphysin-Rvs) domains that dimerize into a banana-shaped structure which can sense membrane curvature and generate membrane tubules (Peter *et al.*, 2004). In mammalian cells the cargo selection complex is associated with combinations of SNX1 and SNX2 with either SNX5 or SNX6 that all contain BAR and PX domains (SNX-BAR) proteins (Wassmer *et al.*, 2009). Docking of the cargo selection complex on membranes requires direct binding with rab7 (Rojas *et al.*, 2008) on early/maturing endosomes, and the affinity of the SNX-BAR subcomplex for PI(3)P in this endosomal membrane domain (Rojas *et al.*, 2008). The Vps29 subunit can recruit TBC1D5, a rab7-GAP whose activity converts rab7 to the inactive GDP form (Seaman *et al.*, 2009) that does not bind retromer.

More recent studies in *Caenorhabditis elegans* and *Drosophila melanogaster* uncovered a distinct retromer complex consisting of the cargo recognition complex and SNX3, an SNX without BAR domain. This functionally divergent retromer is required

for the retrieval of the wnt receptor wntless from endosomes to the TGN (Harterink *et al.*, 2011) and uses the PX domain of SNX3 for binding to membrane. In accordance with the lack of a BAR domain, the SNX3 retromer concentrates wntless cargo in membrane regions that are distinct from the tubular structures of the archetype SNX-BAR retromer and they represent earlier endocytic domains (Harterink *et al.*, 2011).

The existence of an independent second retromer pathway ferrying different cargo from endosomes back to the TGN is a conceptual advance in our understanding of the cellular organization of retrograde transport pathways. Conceivably, the combination of a conserved cargo selection complex with different SNX proteins could generate the requisite diversity for collecting and returning distinct cargo molecules from spatially separated endosomal domains back to the TGN.

To complicate matters further, not all traffic from endosomes back to the TGN involves retromer. Cargo molecules including shiga toxin and TGN38 are retrieved from endosomes to the TGN via mechanisms that operate without retromer deployment, and are only beginning to be understood recently. One of them invokes recruitment of the pleckstrin homology (PH) domain protein evectin-2 to recycling endosome domains enriched in phosphatidylserine, which is essential for the return of shiga toxin and TGN38 to the TGN (Uchida *et al.*, 2011). A more detailed description of this and the other salvage routes to the TGN is covered elsewhere in this volume.

Recycling from Early Endosomes to the Plasma Membrane

Early studies on transferrin recycling suggested that endosomal recycling occurs by default through geometric sorting into tubules which did not seem to need sorting signals in the cargo (Maxfield and McGraw, 2004). Conceptually this represents an oddity against the common and conserved principles that the cell elsewhere uses to sort proteins in transport carriers for vectorial transport (Bonifacino and Glick, 2004). Over the years, however, a plethora of studies converged on the notion that segregation and deviation from the path to lysosomes depends on signals in the cargo for transport from endosomes to such destinations as plasma membrane (Hsu *et al.*, 2012), TGN (Bonifacino and Rojas, 2006), and melanosomes (Theos *et al.*, 2005).

We now will address the recycling routes from endosomes to the plasma membrane. Morphological and biochemical tracer studies using TfR as a marker established the existence of a fast direct recycling route from early endosomes to the plasma membrane and a slow indirect pathway via recycling endosomes (Maxfield and McGraw, 2004). Several small GTPases including arf6, rab4, rab11, and rab35 localize to early endosomes/recycling endosomes and controls distinct stages and modalities of endosome recycling.

Arf6 was originally discovered as a regulator TfR recycling pathway (Peters *et al.*, 1995). It does so at multiple levels including the formation of a ACAP1 coat containing clathrin and the GAP protein ACAP1 that recognizes sorting sequence information in the cytoplasmic tail of cargo proteins (Hsu *et al.*, 2012). Arf6 also interacts with the sec10 subunit of the

octameric exocyst vesicle-tethering complex. Functional studies of this interaction suggest that arf6 specifies delivery of recycling endosome membrane through interaction with the exocyst complex (Prigent *et al.*, 2003).

Rab4 and rab11 activities are sequentially organized. Rab4 is a regulator of fast recycling, while rab11 distribution partially overlaps with rab4 and regulates the slow pathway (Wandinger-Ness and Zerial, 2014). Rab35 also regulates a fast recycling pathway (Allaire *et al.*, 2010) together with arf6 (Chesneau *et al.*, 2012). Rab4 acts upstream of rab11 since endocytosed Tf first meets rab4 and subsequently rab11 (Sönnichsen *et al.*, 2000). The function of rab4 is at the level of formation of recycling vesicles from early endosomes as found by *in vitro* reconstitution assays (Pagano *et al.*, 2004). It does so via recruitment of adaptor complexes of which adaptor protein complex 1 (AP-1) interacts directly (Perrin *et al.*, 2013) and via the effector rabaptin-5a (Deneka *et al.*, 2003) to rab4. The molecular mechanism for this pathway involves a GTPase cascade that is orchestrated by rab4, which results in association of Arl1, type I Arfs and the AP-1, adaptor protein complex 3 (AP-3), and GGA3 (Golgi-localized, γ -adapting ear-containing, ARF-binding protein) adapter complexes to endosomes (D'Souza *et al.*, 2014).

The mechanism of rab11 function in recycling occurs at multiple levels in the pathway. First, through interaction with the sec15 subunit of the octameric exocyst tethering complex (Wu *et al.*, 2005), rab11 can recruit other subunits of the complex to recycling vesicles and thereby regulate fusion at the plasma membrane (Takahashi *et al.*, 2012). Rab11 and its effector rab11-FIP also interact with eps15 homology domain (EHD) ATPase proteins (Naslavsky *et al.*, 2006) that regulate tubule formation and vesiculation (Cai *et al.*, 2013) and endosomal recycling (Pant *et al.*, 2009).

Other aspects of Rab11 function in recycling relate to a role in connecting endosomal membrane to the cytoskeleton through motor recruitment. Rab11 interacts in several ways with myosin V motors for motility of recycling vesicles in the peripheral cytoplasm (Welz *et al.*, 2014). Rab11 is essential for recycling endosome tubule morphogenesis and the distribution of the tubules toward the cell periphery through interaction with the microtubule motor KIF13A (Delevoeye *et al.*, 2014). Interestingly in melanocytes, KIF13A in complex with the AP-1 adapter is needed for the generation and positioning of peripheral recycling endosomal domains required for sorting of melanogenic enzymes to maturing melanosomes (Delevoeye *et al.*, 2009). The relation between recycling endosomes and melanosomes possibly reflects a more common principle that is used in specialized cells with lysosome-related organelles. In several cell types of the immune system including cytotoxic lymphocytes and mast cells, rab 11-positive recycling endosomes supply exocytic machinery to immature lysosome-related organelles that is needed for their maturation and fusion of the latter with the plasma membrane (Menager *et al.*, 2007; Elstak *et al.*, 2011).

Investigations into trafficking pathways of specific cargo molecules as LDL-related protein1 (LRP1) (Van Kerkhof *et al.*, 2005), potassium channels (Lunn *et al.*, 2007) and β 2-adrenergic receptors (Puthenveedu *et al.*, 2010) unveiled a unforeseen role for SNX17 and SNX27 and retromer in recycling of these ligands. SNX17 and SNX27 lack a BAR domain but

Figure 3 Sorting in endosomal exit pathways. Overview of sorting mechanisms within early endosomes (EE) and the connected tubular endosomal network (TEN). For the sake of simplicity the distinct recycling pathways for Transferrin receptor (TfR), LDL receptor-related protein (LRP) and β_2 -adrenergic receptor (β_2 -AR) are drawn from a continuous network of tubules emanating from the EE and from which recycling carriers bud. Sorting complexes for some of the recycling routes to the plasma membrane and retrieval to the trans Golgi network (TGN) are shown. Cargo destined for degradation such as EGFR is concentrated in the bilayered clathrin coat and subsequently sorted into regions from where intraluminal vesicles are formed and budding into the lumen of multivesicular bodies (MVB).

instead contain post synaptic density (PDZ) and FERM (4.1 protein, ezrin, radixin, moesin) domains. The PDZ domain of SNX27 interacts with signals in the cytoplasmic tail of the β_2 -adrenergic receptor (Lauffer *et al.*, 2010) and is needed together with the cargo selection complex for rapid retrieval of the receptor to the plasma membrane (Temkin *et al.*, 2011). Retromer-mediated recycling of β_2 -adrenergic occurs from rab4-associated endosomal tubules that are decorated with F-actin and distinct from the tubules primarily involved in TfR recycling (Puthenveedu *et al.*, 2010).

The actin patches are generated by the multisubunit Wiskott-Aldrich syndrome protein and SCAR homolog (WASH) complex, a nucleation promoting factor that binds Vps35 (Gomez and Billadeau, 2009) and SNX27 (Temkin *et al.*, 2011). WASH activates actin-related proteins 2/3 (Arp2/3) complex and drives actin branching on the endosomal tubules (Derivery *et al.*, 2009). WASH-regulated actin dynamics form a prerequisite for sorting β_2 -adrenergic receptor to the cell surface (Puthenveedu *et al.*, 2010). The extensive interactions between WASH and retromer suggest an attractive model in which actin and retromer-dependent remodeling of the endosomal surface cooperate for efficient recycling.

With this new role of the cargo selection complex in endosomal recycling, the functions of retromer have now diversified beyond those of the SNX-BAR and SNX3 – retromer complexes at the endosome TGN interface. In accord with a central role of SNX27-retromer in endosome recycling, many plasma membrane proteins have been identified that rely on SNX27 for recycling and bypassing of the degradative pathway (Steinberg *et al.*, 2013; Figure 3).

Conclusion and Perspectives

Nature's choice to allocate cellular functions to discrete compartments importantly shaped our thinking of the strategies to decipher the workings of a cell. By taking apart the cell part and studying individual elements, we made fast and great progress in understanding the ramifications of the endo-lysosomal system within the core fabric of life. We charted and partially delineated the complexity of pathways leading to and from this highly dynamic organelle. We also discovered many molecules that safeguard the uninterrupted flow of information within the endosomal system and from the upstream

and downstream neighboring organelles of the trafficking routes.

Given the massive flux of proteins and lipids that enter and leave the endosomal system we need to address now how compartmental integrity is maintained. In other words, how are input and output of the distinct pathways integrated, what is the nature and hierarchy of the control systems that coordinate and achieve homeostasis. These questions also ask for applying control and system theory to provide quantitative information needed for describing and predicting the behavior of the system in terms of response to, for instance, nutritional alterations.

Perhaps related to this problem is the need to explore whether and how the separate protein complexes that regulate endosomal recycling cooperate to sustain a specific pathway. We may ask which of the rab proteins co-organizes the SNX27-retromer pathway. Not only will this bring us closer to an understanding of the organizational principles of exit routes, we may also learn whether the rab7-SNX-BAR retromer co-incidence detection reflects an example of a general principle.

In recent years it has become evident that endosomes directly and functionally interact with the endoplasmic reticulum, the largest cellular compartment and store for ions and lipids. Signaling of the epidermal growth factor (EGF) receptor involves contacts between endosomes and endoplasmic reticulum membrane containing the protein tyrosine phosphatase PTP1B (Eden *et al.*, 2010). Importantly endoplasmic reticulum contacts were recently shown to determine the sites, timing, and efficiency of endosome fission events (Rowland *et al.*, 2014). Conceivably, such contacts may contribute to, or control sorting processes within the endosomal system. Elucidating the molecular principles underlying the contact sites may therefore be of great interest to understand the dynamics of the endosomal system as well as of the endoplasmic reticulum.

The Late Endosome

Introduction

The views on late endosomes have evolved quite significantly since the discovery of a prelysosome compartment (Straus, 1964) and of endosomes defined as a heterogeneous population of endocytic vacuoles (Helenius *et al.*, 1983). Endosomes were originally seen as a succession of transient steps along a gradual maturation process eventually leading to the lysosomes. It became apparent that endosomes along the pathway are morphologically and functionally distinct, with differences in their receptor content (Goldstein *et al.*, 1985; Geuze *et al.*, 1984; Griffiths *et al.*, 1988), acidification properties (Schmid *et al.*, 1988) and membrane dynamics (Bomsel *et al.*, 1990; Aniento *et al.*, 1993), and that early and late endosomes contain a selective set of components, notably RAB GTPases (Chavrier *et al.*, 1990). These observations eventually lead to the notions that early and late endosomes have selective sorting functions in the vacuolar apparatus, as a hub for recycling receptors and a last portal before the lysosomes, respectively. Today, it is becoming apparent that late endosomes function as a key sensing and signaling organelle that informs the cell about its nutrient and supply situation.

The Early/Recycling Endosome Network

The notions of late endosome, multivesicular body (MVB), and lysosome are often blurred, in part because of terminology, but probably also because of differences in the organization of endosomes in plants, fungi, and mammalian cells. To avoid any confusion, we will briefly introduce the general organization of the endocytic pathway across eukaryotes, before discussing the current notions on late endosome organization and functions.

In mammalian cells, endosomes play a central role in controlling the reutilization or degradation of membrane components, and thus regulate fundamental processes, including nutrient uptake, immunity, signaling, adhesion, membrane turnover, defense against pathogens, and development. Components that have been endocytosed by several pathways are delivered to a common early endosome (Figure 1). The V-ATPase, a multi-subunit proton pump (Marshansky and Futai, 2008), acidifies the endosome lumen to a $\text{pH} \approx 6.2$ in early endosomes. At this mildly acidic pH, receptors are uncoupled from their bound ligands so that ligands can be transported toward lysosomes and receptors reutilized via recycling pathways. Housekeeping receptors and other proteins are recycled back to the plasma membrane directly or indirectly via recycling endosome, while other molecules are routed toward the trans-Golgi network (TGN).

From a quantitative point of view, internalization into early endosomes and recycling back to the plasma membrane may well represent the major membrane traffic pathway in mammalian cells (Steinman *et al.*, 1983; Howes *et al.*, 2010). Early

endosomes and recycling endosomes contain selective subsets of lipids and proteins (Bohdanowicz and Grinstein, 2013; Hsu and Prekeris, 2010) and recycling endosomes are slightly less acidic than early endosomes (Yamashiro *et al.*, 1984). Beyond these differences, early and recycling endosomes form extensive networks of interconnected tubulo-cisternal elements that can exhibit a highly reticular organization in some cell types (Geuze *et al.*, 1983; Griffiths *et al.*, 1989; Marsh *et al.*, 1986; Stoorvogel *et al.*, 1996; Tooze and Hollinshead, 1991). Individual early endosome elements also exhibit a high homotypic fusion activity *in vitro* (Gruenberg *et al.*, 1989) and *in vivo* (Roberts *et al.*, 1999; Foret *et al.*, 2012), consistent with the notion that early endosomes form functional networks (Gruenberg and Howell, 1989).

To ensure that the pathways of membrane component reutilization are kept well separated from lysosome targeting – recycling receptors should not cycle through lysosomes – the early endosome functions as the key intracellular sorting station between recycling routes and transport toward lysosome for degradation. Activated signaling receptors and other proteins that need to be downregulated are sorted into luminal invaginations of the early endosome membrane, which are pinched off as free cargo-containing intraluminal vesicles (ILVs). These multivesicular regions detach and become multivesicular endosomes or bodies (Figure 1), which are often referred to as MVBs or ECVs (endosomal carrier vesicles). Eventually, ILVs and their cargo are delivered to lysosomes and degraded. Late endosomes function as a second trafficking hub in the endosomal system, at the crossroad with the autophagy pathway (Choi *et al.*, 2013) and as last sorting station in the membrane trafficking cycle to and from lysosomes, but also to other destinations, including the TGN and the plasma membrane (Bissig and Gruenberg, 2014; Huotari and Helenius, 2011; Raposo and Stoorvogel, 2013).

Biogenesis of the Multivesicular Body

ECV/MVBs function as intermediates during transport between the two-membrane networks formed by early/recycling endosomes and late endosome/lysosomes, respectively (Bissig and Gruenberg, 2013). In contrast to early or late endosomes, ECV/MVBs are not pleomorphic, and exhibit a characteristic and fairly uniform ultrastructure in most mammalian cell types. They appear as large spherical structures with a diameter of approximately $0.5 \mu\text{m}$, which contain a homogenous population of ILVs with a diameter of approximately 50 nm (Razi and Futter, 2006; Pons *et al.*, 2008); 25 nm in yeast cells (Wemmer *et al.*, 2011).

The biogenesis of ECV/MVBs from early endosome elements involves the deformation of the membrane toward the lumen during ILV formation and toward the cytoplasm during recycling tubule formation (Figure 1). Moreover, the membrane remodeling process also requires the expansion of the

Figure 1 The figure outlines the main routes of endocytic membrane traffic. Solutes and membrane proteins, including receptors, and lipids are endocytosed by more than one pathway and these merge in a common early endosome. From there, some components, for example, housekeeping recycling receptors, are recycled to the cell surface directly or indirectly via recycling endosomes. Other proteins and lipids are transported to the trans-Golgi network (TGN), while downregulated signaling receptors are sorted into intraluminal vesicles (ILVs) that bud within the endosome lumen. These multivesicular regions then detach or mature from early endosomes and become free endosomal carrier vesicle (ECV) or multivesicular bodies (MVBs), which are then transported toward late endosomes with which they fuse. A transient intermediate, the endolysosome, is formed upon fusion of late endosomes and lysosomes, while ILVs and other components destined for degradation are eventually packaged in the lysosomes. The figure also illustrates possible pathways toward the plasma membrane followed by lysosome-related organelles (LROs) and multivesicular endosomes in nonspecialized cells.

forming ECV/MVB into a relatively large vacuole. Although this mechanism remains poorly understood, it seems that actin patches nucleated onto early endosomes via the lipid-binding protein AnxA2 drive the process (Mayran *et al.*, 2003; Morel *et al.*, 2009), and that ERM actin-binding proteins and the homotypic fusion and vacuole protein sorting (HOPS) complex may also be required (Chirivino *et al.*, 2011).

During ILV biogenesis, cargo sorting is mechanistically coupled to the membrane deformation process itself (Hurley and Stenmark, 2011), as is the case in other membrane transport steps. The sorting process is initiated by phosphatidylinositol 3-phosphate (PtdIns(3)P), a phosphoinositide generated by the PtdIns 3-kinase VPS34, which is itself an effector of the early endosome GTPase RAB5 (Shin *et al.*, 2005) – small GTPases of the RAB family are selectively associated to a subset of compartments (Galvez *et al.*, 2012) and control the function and identity of intracellular membranes. PtdIns(3)P, which can be hydrolyzed by 3-phosphatases or phosphorylated into PtdIns(3,5)P₂ by the PtdIns(3)P 5-kinase FAB1/PIKfyve

(Odorizzi *et al.*, 1998), serves as a recognition marker on endosomal membranes for PtdIns(3)P-binding proteins. These include in particular the Hrs subunit of the protein complex termed ESCRT-0 (endosomal sorting complex required for transport), which is recruited onto early endosomes via its FYVE PtdIns(3)P-binding domain and which in turn binds and clusters the ubiquitinated signaling receptor molecules. Then, through the sequential action of ESCRT-I, II and III complexes, receptors are collected into nascent ILVs (Hurley and Hanson, 2010; Henne *et al.*, 2011). The ESCRT-III complex directly contributes to the membrane deformation process leading to ILV formation via a mechanism that remains to be established (Hurley and Hanson, 2010; Henne *et al.*, 2011; Hurley and Stenmark, 2011). Plants do not express ESCRT-0 orthologs implying that as-of-yet unidentified adapter molecules must exist to fulfill an analogous cargo selecting function (Contento and Bassham, 2012). Consistent with this notion recent evidence indicates that adapters alternative to Hrs exist in the ESCRT sorting pathway of yeast and

mammalian cells (Bissig and Gruenberg, 2014). Moreover, other factors, in addition to ESCRTs and ESCRT-associated proteins are also involved in ILV biogenesis, including the PtdIns(3)P-binding proteins SNX3 and its homolog SNX12 (Pons *et al.*, 2008, 2011), as well as CD63 in melanosome biogenesis (van Niel *et al.*, 2011). ESCRT proteins are also involved in cytokinesis and virus budding at the plasma membrane, which are membrane deformation processes that share the same topology as ILV formation, and exhibit additional functions perhaps unrelated to membrane trafficking (Slagsvold *et al.*, 2006; Rusten *et al.*, 2012).

Once formed, ECV/MVBs rapidly acidify, eventually reaching pH=5.5, and mediate microtubule-dependent transport toward late endosomes, with which they can undergo fusion, thereby delivering their protein and lipid cargo (Bissig and Gruenberg, 2013; Huotari and Helenius, 2011; Figure 1). The switch from early to late endosomes along the pathway is driven by the conversion from RAB5 to RAB7, which epitomize early and late endosomes, respectively. This process, which is believed to occur on ECV/MVB membranes (Rink *et al.*, 2005), is regulated by the SAND1/MON1–CCZ1 complex (Poteryaev *et al.*, 2010; Kinchen and Ravichandran, 2010). This RAB conversion process is also involved in the mechanism that recruits the retromer to endosomal membranes (Rojas *et al.*, 2008; Seaman *et al.*, 2013) timing protein retrieval to endosome maturation. The membrane fusion specificity, which accompanies the maturation process, is ensured by substituting the class C core vacuole/endosome tethering factor (CORVET) by the late endosomal/lysosomal HOPS complex – a change concomitant with a change from the early to the late endosome SNARE docking/fusion proteins (Solinger and Spang, 2013). The change in membrane identity from early to late endosomes, by remaining well-defined in time and space, ensures that the early/recycling endosome-to-plasma membrane and late endosome-to-lysosome cycles remain topologically and functionally separated.

The Late Endosome–Lysosome Network

Late endosomes contain multivesicular regions, which unlike ECV/MVBs, exhibit highly pleomorphic and complex ultrastructures, including multilamellar or mixed multivesicular/multilamellar regions, depending on the cell type. Although the biophysical and biochemical principles intrinsic to such diverse membrane organization and packing are not known, this situation likely reflects specialized functions of intraluminal membranes in protein/lipid transport and metabolism (Bissig and Gruenberg, 2013). Moreover, in addition to endocytic membrane transport and delivery of Golgi-derived vesicles, autophagosomes represent an additional port of entry into the late endocytic stages of the pathway, and presumably also account for the pleomorphic nature of intraluminal membranes. Autophagy has been described in recent reviews (Choi *et al.*, 2013) and is introduced in another article, and will thus not be discussed further here.

Late endosomes, much like early endosomes, also exhibit high homotypic fusion activity *in vitro* (Bomsel *et al.*, 1989; Aniento *et al.*, 1993) and contain, in addition to multivesicular regions, dynamic tubulo-cisternal elements (Griffiths, 1988,

p. 415; Lebrand *et al.*, 2002; Zhang *et al.*, 2001; Ko *et al.*, 2001; Brankatschk *et al.*, 2011). The PX-containing protein SNX16 is selectively found on late endosome tubules and absent from multivesicular regions (Brankatschk *et al.*, 2011), consistent with the existence of different membrane domains in late endosomes (Barbero *et al.*, 2002) and with the mosaic organization of intracellular membranes (Gruenberg, 2001). Interestingly, J774.2 macrophages and phorbol ester-treated macrophages contain an abundant network of tubular lysosomes (Phaire-Washington *et al.*, 1980; Swanson *et al.*, 1987; Heuser, 1989), which may be of late endosomal origin (Rabinowitz *et al.*, 1992; Mrakovic *et al.*, 2012) perhaps under the control of the lipid kinase PI4KIIIb (Sridhar *et al.*, 2013). Presumably, tubular lysosomes in macrophages correspond to an extreme situation in the dynamic equilibrium between late endosomes and lysosomes.

Indeed, late endosomes and lysosomes rapidly exchange membrane components and solutes *in vivo* (Deng and Storrie, 1988; Jahraus *et al.*, 1994). These observations led to the predominant model that the two organelles undergo transient fusion and fission events, allowing an interchange of material (both cargo and enzymes). More recently with live imaging experiments, combined with ultra-structural analysis, transient (kiss-and-run) fusion of the organelles was proposed (Luzio *et al.*, 2007). The prevailing notion is that late endosomes and lysosomes form upon fusion a transient hybrid organelle, that can be referred to as endo-lysosome, which is converted into classical secondary or dense lysosomes (Mullock *et al.*, 1989; Griffiths *et al.*, 1990; Luzio *et al.*, 2007; Huotari and Helenius, 2011).

The distinction between late endosomes and lysosomes at the molecular level is further blurred by the fact that, to the best of our knowledge, there is no lysosome protein that is not also present in late endosomes. The main constituents of the membrane of both compartments are the highly sialylated membrane proteins LAMP1 and LAMP2 (Griffiths *et al.*, 1988), which form a protective glycocalyx-like layer on the luminal side of the membrane against lysosomal enzymes. While late endosomes and lysosomes are difficult to discriminate from each other at the molecular level, they can be distinguished by their physical properties and ultrastructure. In contrast to multivesicular and tubulo-cisternal elements of late endosomes, the classical secondary lysosomes are spherical electron-dense structures, originally referred to as dense bodies of variable size and content depending on the diet (Bainton, 1981; de Duve, 2005). Similarly, secondary lysosomes exhibit a high density on gradients and can be separated from endosomes by subcellular fractionation. In fact, before the discovery of late endosomes, newly synthesized lysosomal enzymes were known to transit via a compartment referred to as light lysosomes because of its low buoyancy on gradients before reaching secondary lysosomes – it is now apparent that light lysosomes are late endosomes (Brotherus and Renkonen, 1977; Sahagian and Neufeld, 1983; Aniento *et al.*, 1993; Kobayashi *et al.*, 1998; Tjelle *et al.*, 1996). Conversely, lysosomes can be defined biochemically as containing the bulk of the fully mature, dephosphorylated lysosomal enzymes.

Specialized cell types contain unique secretory compartments, collectively referred to as lysosome-related organelles

(LROs), which share some endosomal and lysosomal features and are involved in numerous processes, including pigmentation, hemostasis and immunity (Marks, 2013). In nonspecialized cells, conventional late endocytic and multivesicular compartments can acquire the capacity to undergo fusion with the plasma membrane upon a transient rise in cytosolic calcium, in a process that may depend on synaptotagmin VII (Rodriguez *et al.*, 1997; Rao *et al.*, 2004). This process may be involved in plasma membrane repair (Andrews, 2000), and is controlled by the master regulator of late endocytic functions, the transcription factor EB (TFEB) (Settembre *et al.*, 2013b). However, endo-lysosome exocytosis, which is reminiscent of LROs, may occur from more than one population of donor endosomes and may also fulfill other secretory functions (Laulagnier *et al.*, 2011), including the release of exosomes (Raposo and Stoorvogel, 2013) and storage materials in the lysosomes of mucopolidiosis type IV cells (LaPlante *et al.*, 2006).

Endosomes in Plants and Fungi

Late endosomes have sometimes been defined as MVBs in mammalian cells, but this notion is very confusing. Multivesicular regions are found at all stages of the endocytic pathway, and conversely, as we have seen above, late endosomes cannot be reduced strictly to their multivesicular elements. Part of the confusion also stems from marked differences in the organization of the endosomal system in plant, yeast and mammalian cells. In plant cells, the trans-Golgi network fulfills the role of the early endosome, being the first site for delivery of endocytosed material. Consequently, RABA1 GTPases, which belong to the large group of RAB11 homologs, are involved in TGN-to-plasma membrane transport in higher plants (Asaoka *et al.*, 2012), while RAB11 controls endosome-to-plasma recycling in mammalian cells. However, this hybrid organelle is not completely analogous to the early endosome of mammals as plants completely lack RAB4 and likely the rapid recycling pathway dependent on it (Saito and Ueda, 2009). It has been proposed that the trans-Golgi network then matures into an MVB via an annexin-dependent mechanism (Scheuring *et al.*, 2011; Viotti *et al.*, 2010) reminiscent of that found in mammalian cells (Mayran *et al.*, 2003; Morel *et al.*, 2009). Eventually, the MVB fuses with the plant vacuole, which plays the role of lysosomes in animal cells.

Unlike plants, yeast cells do not seem to contain a true hybrid early endosome/TGN-like organelle, but some endosomal functions in mammalian cells are linked to the Golgi in yeast cells. The class D VPS genes were characterized by the accumulation of Golgi-derived carrier vesicles laden with vacuolar transmembrane proteins (Raymond *et al.*, 1992). This class includes many of the canonical early endosomal proteins of mammalian cells including RAB5 (VPS21) and a VPS21 exchange factor VPS9, syntaxin 7 (PEP12/VPS6), the PtdIns 3-kinase VPS34 and its regulator VPS15, VPS19 (related to Rabenosyn-5), as well as the RAB5/VPS21 and PtdIns(3)P interacting protein VAC1 (Tall *et al.*, 1999). Consistent with this notion, several of these proteins have been localized to the TGN in yeast, implying that many of the sorting functions

ascribed to the early endosome may indeed take place in the Golgi – and earlier studies of the yeast RAB5 homologs already suggested the existence of an intersection of the endocytic and vacuolar sorting pathways (Singer-Kruger *et al.*, 1994).

Moreover, in contrast to plants, the delivery of endocytosed material to the prevacuolar compartment (late endosome) occurs via a Golgi-independent route in yeast cells (Riezman, 1985; Vida and Emr, 1995). Electron microscopy studies have shown that tracers internalized in yeast cells appear sequentially in structures that contain the tSNARE Tlg1p and then in the prevacuolar compartment that contains the tSNARE Pep12 (Prescianotto-Baschong and Riezman, 2002). However, the yeast and mammalian endosomal pathways are not equivalent and comparisons should be made with care. Although there is no doubt that basic machineries are conserved, and that studies in yeast cells have greatly helped unravel the mechanisms that regulate endocytic membrane transport, yeast cells seem to lack a compartment with the molecular or functional characteristics of early endosome in mammalian cells. In yeast, there is no evidence for the existence of direct recycling pathways that bypasses the Golgi, like the major mammalian routes of early endosome-to-plasma membrane recycling. In fact, recycling is regulated in mammalian cells by the small GTPases RAB11 and RAB4, with RAB4 controlling a faster route. Yeast cells do not express a RAB4 homolog, much like plant cells (Pereira-Leal and Seabra, 2001), and the RAB11 homologs Ypt31p/32p appear to control a pathway of protein recycling from the endosome to the Golgi (Chen *et al.*, 2005).

One should also bear in mind that recycling, secretion or exosome release can occur in mammalian cells from late multivesicular endosomes (Andrews, 2000; Laulagnier *et al.*, 2011; Marks *et al.*, 2013; Raposo and Stoorvogel, 2013) and that several lines of evidence suggest that mammalian cells contain more than one population of ILVs with different fates (discussed below). By contrast, yeast ILVs seem to have the vacuole as single destination and there is no evidence for direct pathways from the prevacuolar compartment containing the tSNARE Pep12 to the yeast plasma membrane.

Lysosome Enzymes and Lysosomal Membrane Proteins

It has long been appreciated that endosomes contain active lysosomal enzymes even at very early stages of the pathway (Diment and Stahl, 1985). Most newly synthesized lysosomal hydrolases carry a unique Man6P recognition motif and in the TGN bind their cognate Man6P receptors. From there, they are transported via coated vesicles presumably to early endosomes. In endosomes, the enzymes are released from the receptors at the low endosomal pH, and then packaged in lysosomes (Braulke and Bonifacino, 2009). The current view is that the Man6P receptors recycle from maturing endosomes back to the TGN via the retromer complex in a process that requires both RAB5 and RAB7. An additional route exists to transport the receptor from late endosomes to the Golgi, which involves the small GTPase RAB9 and its effectors (Ganley *et al.*, 2004, 2008) – whether proteins other than Man6P receptors can exploit this route is still not known. The role of this route is underscored by recent reports showing the salmonella protein sifA blocks the traffic of M6PR receptors by

sequestration of RAB9 (McGourty *et al.*, 2012). Man6P receptor retrieval to the TGN may thus occur by two sequential pathways: it begins in early endosomes via RAB5 and RAB7 and continues in late endosomes via RAB9 (Seaman, 2012; Rojas *et al.*, 2008; Johannes and Popoff, 2008; Bonifacino and Hurley, 2008; Pfeffer, 2011; Anitei and Hoflack, 2011). Lysosomal enzymes, in turn, undergo a maturation process, including dephosphorylation and often proteolytic processing, and become fully active at the low acidic pH of late endosomes and lysosomes (approximately 5.5–5.0).

The newly synthesized forms of the late endosome and lysosome transmembrane proteins, including LAMP1 and LAMP2, are transported from the TGN via a pathway different from that used by hydrolases, involving the adapter complex AP3 (Saftig and Klumperman, 2009). It has recently become apparent that lysosome biogenesis (Sardiello *et al.*, 2009), as well as autophagy (Settembre *et al.*, 2011), are under the control of the master regulator TFEB – a process that reveals how lysosomes can adapt to environmental cues (Settembre *et al.*, 2013b), and that will be discussed below. Numerous human diseases are in fact associated with defects in lysosome membrane proteins (Saftig and Klumperman, 2009; Ikonen and Holtta-Vuori, 2004) and enzymes (Futerman and van Meer, 2004; Sardiello and Ballabio, 2009; Schulze and Sandhoff, 2011). A defective enzyme causes a lysosomal storage disease because of the pathological accumulation of the corresponding substrate, which eventually jams the endolysosomal system. Some lipid storage diseases however are not caused by a defective enzyme, including the cholesterol storage disease Niemann-Pick type C, caused by mutations in the NPC1 or NPC2 genes whose functions are not clearly established (Ikonen and Holtta-Vuori, 2004; Vanier, 2010) and Mucopolipidosis type IV, which is caused by mutations in the cation channel mucopolipin-1 (Wakabayashi *et al.*, 2011).

Composition and Fate of Intraluminal Membranes

Several lines of evidence show that intraluminal membranes of late endosomes exhibit differences in their protein/lipid composition, fate and function. Typically, late endosomes of mammalian cells contain high amounts (approx. 15Mol%) of the unconventional phospholipid lysobisphosphatidic acid (LBPA) or bis(monoacylglycerol)phosphate (BMP) (Kobayashi *et al.*, 1998) – the lipid has not been detected in yeast. LBPA is abundant in ILVs of late endosomes after immunogold labeling of cryosections, and is not detected elsewhere in the cell, including early endosomes and ECV/MVBs (Kobayashi *et al.*, 1998; Bissig and Gruenberg, 2013). By contrast, PtdIns(3)P is generated on early endosomes, as we have seen above, where it controls the onset of the ESCRT pathway. Electron microscopy studies showed that PtdIns(3)P is also present in ILVs of ECV/MVBs and to a lesser extent late endosomes – where it does not seem to colocalize with LBPA (Gillooly *et al.*, 2000). LBPA and PtdIns(3)P thus appear to show mirror image-like distribution along membranes of the endocytic pathway.

LBPA is primarily present as the 2,2'-dioleoyl isoform, which is biologically active (Kobayashi *et al.*, 1998; Matsuo *et al.*, 2004; Chevallier *et al.*, 2008), but thermodynamically unstable as the fatty acid chains can migrate to form 3,3'-LBPA

(Chevallier *et al.*, 2000; Kobayashi *et al.*, 2002). The position of LBPA fatty acyl chains likely modulates its biological functions, by dramatically changing the overall structure (Goursot *et al.*, 2010). The pathway of LBPA synthesis and degradation is not clearly established (Bissig and Gruenberg, 2013), but it is a poor substrate for lipases and phospholipases presumably because it is stereoisomeric to other naturally occurring phospholipids (Brotherus *et al.*, 1974; Tan *et al.*, 2012). It has been shown that LBPA has the intrinsic capacity to deform membranes *in vitro* (Matsuo *et al.*, 2004), a situation which presumably reflects the role of LBPA during ILV formation within late endosomes *in vivo*. In addition, LBPA interacts directly with the ESCRT-associated protein ALIX (Bissig *et al.*, 2013), consistent with the notion that both LBPA and ALIX play a direct role in ESCRT-dependent ILV formation within late endosomes (Falguières *et al.*, 2008; Bissig and Gruenberg, 2014). It seems that, in addition to the ESCRT-0 subunit HRS, other adapters, including ALIX, may recruit cargo proteins into nascent ILVs presumably at sequential steps of the pathway (Bissig and Gruenberg, 2014).

Other Destinations: All Roads Do Not Lead to the Lysosomes

While signaling receptors sorted into ILVs are targeted to lysosomes for degradation, other molecules present in late endosomal intraluminal membranes are not rapidly turned over, like LBPA itself or proteins of the tetraspanin family that share four transmembrane segments and two conserved extracellular loops (Engering *et al.*, 2003). In addition, some proteins in transit through late endosomal intraluminal membranes including the Man6P receptors (Griffiths *et al.*, 1988; Kobayashi *et al.*, 1998) and the tetraspanin CD63 in endothelial cells (Kobayashi *et al.*, 2000) escape delivery to lysosomes (Braulke and Bonifacino, 2009) – again in contrast to signaling receptors. Finally, evidence shows that, in mammalian cells, some ILVs and their cargo are not destined for degradation. Microvesicles of ILV origin can be released as exosomes into the extracellular space after fusion of secretory endo-lysosomes with the plasma membrane (Raposo and Stoorvogel, 2013). While exosomes may (Denzer *et al.*, 2000) or may not (Wubbolts *et al.*, 2003) contain LBPA, ALIX itself is found in exosomes (Thery *et al.*, 2009; Mathivanan *et al.*, 2012). However, the role of ALIX in exosome biogenesis appears to be cell type dependent. In a mouse oligodendroglial cell line, exosome biogenesis was found to be ceramide-dependent and ALIX- and ESCRT-independent (Trajkovic *et al.*, 2008), while in MCF-7 cells, exosome biogenesis was promoted by syndecan-syntenin in an ALIX and ESCRT-dependent manner (Baietti *et al.*, 2012). Similarly, the formation of exosomes in human retinal pigmented epithelial 1 (RPE1) cells requires SNX3, consistent with its role in ILV formation (Pons *et al.*, 2008), as well as ALIX and the ESCRT-I subunit TSG101 (Abrami *et al.*, 2013).

In addition to ILV formation and exosome secretion, both ALIX and LBPA were also shown to be involved in the penetration of some pathogenic agents into the host cell cytoplasm, including anthrax toxin lethal factor (Abrami *et al.*, 2004, 2013), vesicular stomatitis virus (VSV) (Bissig *et al.*, 2013; Le Blanc

et al., 2005; Luyet *et al.*, 2008), Old World arenaviruses (Pasqual *et al.*, 2011). Although the mechanism remains to be elucidated (Bissig and Gruenberg, 2014), it has been proposed that anthrax toxin lethal factor and VSV RNA are released into the ILV lumen in order to reach late endosomes without encountering a degradative environment (Gruenberg and van der Goot, 2006). There, ILV back-fusion with the limiting membrane would ensure toxin or RNA release into the cytoplasm in a process controlled by LBPA, ALIX and ESCRTs. Proteins and lipids that transit through late endosomes, including low density lipoprotein (LDL)-derived cholesterol (Kobayashi *et al.*, 1999; Chevallier *et al.*, 2008) may utilize this ILV back-fusion as an escape route from lysosomes (Falguières *et al.*, 2012). It should be noted that ILV back-fusion has only been observed in LBPA-containing late endosomes, and consistent with this notion, there is no evidence for the existence of a similar escape pathway in yeast cells, which may not contain LBPA.

The Late Endosome: A Signaling Platform

Evidence is accumulating that late endosomes and lysosomes play an essential role as sensing and signaling organelles. In mammalian cells, late endosomes regulate the intracellular trafficking of LDL-derived cholesterol – LDL particles being the main source of cholesterol in the cells of most mammalian tissues. They are endocytosed by the LDL receptor, and, after uncoupling from the receptor, are transported to late endosomes, where hydrolysis of the ester by the lysosomal acidic lipase, releases free cholesterol (Goldstein *et al.*, 1985). Cholesterol then needs to reach its intracellular destinations, in particular the endoplasmic reticulum (ER) where the SREBP-dependent feedback regulation of cholesterol synthesis and uptake takes place (Brown and Goldstein, 1997).

Once de-esterified in the late endosome lumen, free cholesterol rapidly partitions into nearby membranes, presumably containing LBPA, due to its low partition coefficient. From there, it is exported to its cellular destinations via an export mechanism that remains to be elucidated. Mutations in the NPC1 and NPC2 proteins cause the cholesterol storage disorder Niemann-Pick C (Loftus *et al.*, 1997; Naureckiene *et al.*, 2000), but the precise functions of these proteins is being debated (Kwon *et al.*, 2009; Ikonen and Holttä-Vuori, 2004; Lloyd-Evans *et al.*, 2008). The disease can be phenocopied at the cellular level by conditions that interfere with the functions of LBPA (Kobayashi *et al.*, 1999). In fact, both cholesterol export from late endosomes and viral capsid release share the same LBPA-dependence and both processes also depend on ALIX, suggesting that cholesterol is exported to the endosome limiting membrane via ILV back-fusion (Bissig and Gruenberg, 2014), as discussed.

Experimental evidence supports the existence of ER-late endosome contact sites, which may be involved in signaling and regulatory functions. It has been proposed that ER-resident tyrosine phosphatase PTB1B contributes to dephosphorylate activated EGF receptor present in endosomes (Haj *et al.*, 2002; Eden *et al.*, 2010). More directly, the ER-resident protein oxysterol-binding protein ORP5 was shown to interact physically with NPC1, suggesting that this association may mediate cholesterol exchange (Du *et al.*, 2011). Another oxysterol-

binding protein ORP1L and its partner, the ER protein Vap-A, were proposed to regulate endosomal motility via a tripartite complex with RAB7 and its effector RILP, driving minus-end directed motility of endosomes mediated by the dynein/dynactin motor (Rocha *et al.*, 2009; Vihervaara *et al.*, 2011). These authors recently demonstrated a role for this complex in late endosomal tethering and fusion via interaction with the HOPS complex (van der Kant *et al.*, 2013). Interestingly, the same Vap-A protein has been shown to promote ER-LE contact via interaction with the proteins STARD3/MLN64 and STARD3NL/Mentho (Alpy *et al.*, 2013) – two proteins involved in cholesterol transport to mitochondria (Zhang *et al.*, 2002; Charman *et al.*, 2010). Recent studies, based on the cholesterol-modulating adenoviral protein RID α , which interacts with RAB7 and ORP1L, propose that ORP1L could indeed be essential for the transport of LDL-derived cholesterol to its regulatory pool in the ER (Cianciola *et al.*, 2013).

In addition to its central role in cholesterol transport, late endocytic compartments play a fundamental and evolutionary conserved role in nutrient sensing and the consequent adaptation of cell growth/differentiation and metabolism (Settembre *et al.*, 2013b). The master regulator is the Ser/Thr kinase mammalian target of rapamycin (mTOR), assembled in the multi-protein complex mTOR complex 1 (mTORC1) which integrates nutrient availability with other environmental cues, such as growth factors signals and cellular stress, at the surface of late endosomes (Jewell *et al.*, 2013). A series of signaling events converge to regulate mTORC1 (Jewell *et al.*, 2013; Dibble and Manning, 2013) but a crucial event – and prerequisite for activation – is mTORC1 translocation to late endosome/lysosomal membrane promoted by nutrient availability. Translocation is regulated by the RAG GTPases and its effector complex regulator and is promoted by the presence of both free amino acids (Sancak *et al.*, 2010) and glucose (Efe-yan *et al.*, 2013). Interestingly, the TORC1 complex in yeast stably resides in the vacuole, but the mechanism of regulation by GTPases in nutrient-dependent manner is otherwise very similar (Binda *et al.*, 2009; Kogan *et al.*, 2010). How amino acids in the endosome lumen are sensed by the Rag/regulator complex is still not perfectly clear. The V-ATPase is clearly essential for activation (Zoncu *et al.*, 2011; Bar-Peled *et al.*, 2012) but it is not established whether it directly transmits the signal, independently from its proton pump activity (Zoncu *et al.*, 2011) or whether the V-ATPase indirectly promotes the activity of the proton-dependent amino acid exporter PAT1 (Heublein *et al.*, 2010; Ogmundsdottir *et al.*, 2012). In addition to its role in the regulation of cellular metabolism (Duvel *et al.*, 2010), mTORC1 also plays a direct role in lipid metabolism through modulation of SREBP both at the transcriptional and post-translational level (Porstmann *et al.*, 2008; Peterson *et al.*, 2011; Owen *et al.*, 2012), representing another direct link between the endosomal system and the regulation of lipid metabolism. In addition, mTORC1 also regulates the nuclear translocation and activation of TFEB (Martina *et al.*, 2012; Roczniak-Ferguson *et al.*, 2012; Settembre *et al.*, 2012), the master regulator of lysosome biogenesis (Sardiello *et al.*, 2009), which also controls autophagy (Settembre *et al.*, 2011) and lipid homeostasis (Settembre *et al.*, 2013a). Conversely, mTORC1 also appears to regulate lysosome reformation after autophagy (Yu *et al.*, 2010).

Signaling from Endosomes

Endocytosis

Endocytosis is a process whereby cells uptake material from the surface by an inward fold of the plasma membrane (invagination) followed by internalization in membrane-bound vesicles called endosomes. These membrane-bound organelles are important carriers of plasma membrane components and extracellular ligands ingested by endocytosis and function to pass their cargo to lysosomes for degradation. However, not all endocytosed cargo is degraded and a major sorting step occurs in the early endosomes. Depending on the specific receptors and their ligands the endocytosed receptor can: (1) dissociate from the ligand (that will be degraded) and return to the plasma membrane, (2) remain ligand bound and become degraded, or (3) recycle with its ligand intact (e.g., transferrin receptor). Endocytosis can be a constitutive process whereby plasma membrane receptors such as integrins and transferrin receptors are internalized, sorted in early endosomes and returned back to the plasma membrane to engage new ligand molecules. Alternatively, receptor endocytosis can be actively triggered by ligand binding and this process is usually coupled to ligand-induced receptor activation and signaling. Receptor tyrosine kinases (RTKs) activated by external soluble growth factors typically undergo ligand-induced endocytosis and are subsequently degraded or recycled depending on the internalization route and the ligand.

Signaling Endosomes

The classical view of endosomes, in RTK signaling, regarded endocytosis solely as a means to terminate plasma membrane signals and to downregulate plasma membrane receptor availability through targeted receptor degradation. However, this traditional outlook is now being challenged as endocytosed receptors are frequently detected in endosomes in ligand-bound and active states suggesting persistent signaling post-endocytosis. Pioneering work from nearly two decades ago exploited a dynamin mutant that blocks all endocytosis and demonstrated that full activation of signaling pathways downstream of the epidermal growth factor receptor (EGFR) requires endocytosis (Vieira *et al.*, 1996). Today, a mounting body of evidence shows that endocytosis is linked to nearly all aspects of cellular signaling and that endosomes should be viewed as important intracellular platforms for signal transduction. In addition, the coordinated functions of the endocytic machinery and signaling pathways are critical in maintaining homeostasis in many different cell types and conditions.

Endosomes fulfill multiple functions to support and regulate cell signaling. These are depicted in Figure 1 and involve the following major regulatory mechanisms. Endocytosis functions to: (1) terminate plasma membrane signaling either via receptor degradation or via compartmentalization of the receptors away from plasma membrane-specific signaling

effectors, (2) limit bioavailability of cell surface receptors, (3) generate specific signals unique to the endosomal compartment, (4) target signaling in response to different ligands or ligand concentrations, (5) sustain signaling initiated at the plasma membrane, and (6) facilitate signal propagation over long distances that are beyond the limits of passive diffusion (Figure 1). In this article we will describe these general principles and some relevant biological examples related to these specific signaling subsets. For more detailed information we refer the reader to Table 1 (summary of endosome signaling pathways reported for different receptors) and to several in-depth and excellent reviews on this topic (Sigismund *et al.*, 2012; Benzing *et al.*, 2013; Scita and Di Fiore, 2010; Goh and Sorkin, 2013).

Different Cell Types Employ Signaling Endosomes for Distinct Purposes

The majority of our knowledge and evidence for the important biological role of signaling endosomes is derived from cell types like epithelial cells, fibroblasts, and cancer cells. In the remaining part of this article we will focus on describing examples from these cell types in more detail. However, other cell systems also rely on specific forms of endosomal signaling to facilitate their unique biological functions. In neurons signals initiated at the nerve terminals by neurotrophic receptors must be transmitted long distances to the neuronal body and nucleus. In fact the hypothesis of signaling endosomes was introduced based on the observation that nerve growth factor (NGF) induced endocytosis of its tyrosine kinase receptor (TrkA) and the resulting internalized ligand–receptor complex remained active in endosomal compartments (Grimes *et al.*, 1996). Endosomal NGF-TrkA undergo retrograde transport via microtubule and motor-protein based mechanisms to the cell body and signal to extracellular signal-regulated kinase isoforms 1/2 (ERK1/2) and phosphatidylinositol 3-kinase/protein kinase B (PI3K/Akt) pathways to promote cell survival (Howe and Mobley, 2005).

In T cell signaling endocytosis is strongly linked to T cell activation in such a way that the entire endocytic machinery is rearranged in these cells upon activation. T cell receptor (TCR) activation is triggered by the antigenic peptide displayed by the major histocompatibility complex (MHC) on antigen-presenting cells generating an immunological synapse between these cells. TCR is continuously endocytosed from the plasma membrane and returned to the cell surface via recycling endosomes (in a pathway overlapping with the transferrin receptor). This trafficking is critical for TCR accumulation in the immunological synapse (Das *et al.*, 2004) demonstrating that endocytosis contributes to T cell activation. In addition, T cells release cytoplasmic vesicular signaling components, such as Lat and Lck, to the forming immunological synapse in response to TCR activation to trigger efficient TCR signaling.

Figure 1 The various roles of endocytosis in cell signaling. Endocytosis of ligand-activated plasma membrane receptors can have different effects on signaling. (1) The ligand-induced receptor signal initiated at the plasma membrane can be terminated by endocytosis either by directing the receptor–ligand complex for degradation or due to a change in membrane composition, for example, PI(4,5)P₂ (PIP₂) (required for the plasma membrane signal) conversion to PI(3)P in endosomes. (2) Endocytosis can also limit the number of available receptors at the plasma membrane and thus reduce signaling. (3) The signal initiated at the plasma membrane can be altered or fine-tuned by ligand–receptor internalization resulting in the generation of a new signal. (4) In some cases if the ligand-induced plasma membrane signal is not strong enough, endocytosis and translocation of the signaling receptor closer to the nucleus will rescue the outcome by increasing the local signal intensity. (5) Perhaps the most common role for endocytosis is to sustain signaling after internalization and thus amplify the information. (6) Sustained growth factor signaling and active transport of endosomes, as opposed to random diffusion, particularly in the case of nerve cells, is crucial for transmitting signals from nerve terminals to distant nuclei. For more specific details and examples of endosome signaling for different receptors the reader is referred to [Table 1](#).

Subsequently, signaling endosomes containing active Lck, Lat, and phosphorylated receptors are generated to maintain TCR signaling (described in detail in [Benzing *et al.*, 2013](#)).

Endocytic Routes Specify Signaling Outcome

Endocytosis in mammalian cells is regulated by multiple classes of plasma membrane invaginations differing in their biological function, composition, and cargo recruitment. These can be divided into two major classes, clathrin-mediated endocytosis (CME) and non-clathrin endocytosis (NCE) ([Doherty and McMahon, 2009](#)). CME of plasma membrane cargo involves the specific recruitment of cargo receptors, through interaction with adapter proteins, to clathrin-coated pits (CCPs). Clathrin polymerization drives plasma membrane invagination to eventually form an endocytic vesicle in a dynamin-dependent manner. NCE is a more general term for a number of different pathways that are all clathrin-independent but dynamin dependent and here we will only present examples of caveolae-mediated endocytosis. Several plasma membrane receptor classes are known to undergo both CME and NCE depending on the context. Interestingly, the

internalization route can influence the endosomal signaling of the receptors and elicit differential biological signaling outcomes dependent on the external stimuli ([Figure 2](#)). Transforming growth factor beta receptor (TGFβR) can undergo both CME and NCE. Upon TGFβ stimulation the receptor traffics either to early endosome antigen 1 (EEA1)-positive endosomes via CME or to caveolin-positive structures via NCE. This defines the signaling outcome such that the clathrin-mediated endocytosed receptor couples to zinc finger domain found in Fab1 (FYVE) domain containing adapter protein SMAD anchor for receptor activation (SARA) and is routed to signaling-active endosomes, whereas the receptor entering via the NCE is targeted for ubiquitination and degradation ([Di Guglielmo *et al.*, 2003](#)). In the case of EGFR signaling the receptor is endocytosed only through CME if the ligand, EGF, is present in low concentrations. Following CME EGFR is trafficked to signaling endosomes and recycled to the plasma membrane to sustain signaling and minimize degradation. Conversely, at least in some cell types, high EGF levels induce additional NCE of EGFR resulting in receptor degradation ([Sigismund *et al.*, 2008](#)).

It is important to note that NCE does not necessarily lead to receptor degradation and CME to endosomal signaling.

Table 1 Summary of endosome signaling pathways reported for different receptors

Receptor type	Receptor	Ligand	Proposed outcome of endosome signaling	Proposed requirements for signaling	Notes and references
Receptor tyrosine kinases (RTKs)	Met	HGF	Sustained STAT3 phosphorylation and activation in the nucleus	Trafficking to perinuclear compartment	- Strength of STAT3 activation is receptor dependent - Endocytosis propagates weak STAT3 signal following Met activation (Kermorgant and Parker, 2008) - Biochemical fractionation revealed activated EGFR and downstream effectors (components of Ras activation pathway: Grb2, Shc, and SOS) in endosomes (Vieira et al., 1996) - RTK signaling proteins isolated from endosomes using magnetic EGF-coated microbeads (Li et al., 2005) - Targeting endocytosis blocks ERK activation by several RTKs (Vieira et al., 1996)
	EGFR	EGF	Full EGFR phosphorylation for activation of MAPK pathway	Rab5 and APPL positive endosomes	- Intracellular localization of activated EGFR, PIP₂, and lipid products of the PI3K pathway tracked in living cells using green fluorescent protein tag - PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ not detected in EGFR positive vesicles consistent with lack of accessible PIP₂ (Haugh and Meyer, 2002)
	EGFR	EGF	Attenuation of PI3K and PLC- γ signaling	Lack of PIP ₂ in endosome membranes	- TGFα-EGFR association is more pH-sensitive than EGF-EGFR and is disrupted in endosomes - Favors recycling of internalized EGFR rather than degradation (French et al., 1995; Ouyang et al., 1999; Sorkin and von Zastrow, 2002) - VEGFR is sequestered away from plasma membrane phosphotyrosine phosphatases (Lanahan et al., 2010)
	VEGFR	VEGF	VEGFR protected from dephosphorylation and PLC- γ /MAPK signaling prolonged	EEA1 positive endosomes	- Pool of ligand-bound internalized PDGFR is active and tyrosine phosphorylated (Sorkin et al., 1993) - Promotes cell survival and proliferation through Grb2, SHC, PLC-γ1, and p85α subunit of PI3K in endosomes (Wang et al., 2004) - Evidence for co-receptor function during endocytosis: - PDGFR and LRP (Newton et al., 2005) - PDGFR and ephrinB (Nakayama et al., 2013)
	PDGFR	PDGF	PDGFR signaling	CME and NCE endocytosis	

(Continued)

Table 1 Continued

Receptor type	Receptor	Ligand	Proposed outcome of endosome signaling	Proposed requirements for signaling	Notes and references
G-protein-coupled receptors (GPCRs)	TrkA receptor	NGF	Sustained MAPK signaling, activation of Rap1, and retrograde transport of survival signals	Rab5 and EEA1 positive endosomes	● PDGFR endocytosis is dependent on ligand concentration (De Donatis <i>et al.</i>, 2008): ○ Low PDGF – CME – favors cell migration ○ High PDGF – NCE – favors cell proliferation ● Neurotrophin–Trk complexes associate with endosomes and are necessary for signal transduction, for example, MAPK activation (Zweifelf <i>et al.</i>, 2005; Delcroix <i>et al.</i>, 2003; York <i>et al.</i>, 1998; York <i>et al.</i>, 2000; Wu <i>et al.</i>, 2001) ● Retrograde transport of complexes occurs in EEA1 and Rab5 endosomes ● Endosomal signaling promotes cell survival (Grimes <i>et al.</i>, 1996) ● Rapid formation of intracellular vesicles containing EphB–ephrinB complexes in cells ● Contact inhibition is reduced if endocytosis is inhibited or if either EPH or ephrin are missing cytoplasmic domains ● See Review (Egea and Klein, 2007) ● Phosphorylated insulin receptor found in endosomes (Baass <i>et al.</i>, 1995) ● RTK signaling proteins isolated from endosomes using magnetic insulin-coated microbeads (Li <i>et al.</i>, 2005) ● Overexpression of mutant dynamin inhibits insulin-mediated activation of ERK/MAPK 1/2 (Ceresa <i>et al.</i>, 1998) ● Arrestins have two other functions: 1. Arrestins 2 and 3 (main isoforms outside the visual system) act as regulated endocytic adaptors promoting GPCR-coated pit association 2. Bind various components of the MAPK modules and appear to act as scaffolds for MAPK signaling (Leikowitz and Shenoy, 2005; Moore <i>et al.</i>, 2007) ● Endocytosis of G-protein rather than the receptor itself is important for endosome signaling of GPCR (Garcia-Regalado <i>et al.</i>, 2008; Sorkin and von Zastrow, 2009)
	EPH	Ephrin	Activation of Rho GTPases, changes in actin cytoskeleton and contact-mediated repulsion of neighboring cells	Not indicated	
	Insulin receptor	Insulin	MAPK signaling	Not indicated	
	β 2AR	Agonist isoproterenol	Activation of ERK1, ERK2, and Jun N-terminal kinase	CME and requires β -arrestins	
	Specific GPCR not indicated	LPA	PI3K and Akt activation	G-protein $G\beta\gamma$ 2 translocation to endosomes and binding to Rab11A following GPCR activation	

Serine/threonine kinase receptors	Fz1 (distantly related to GPCRs)	Wnt	Stabilization of cytoplasmic β -catenin	CME	- Endocytosis of Fz1/Wnt/Arrow complexes into clathrin-coated pits is promoted by the receptor associated protein Dvl - Dvl binding to AP2 appears to be critical for receptor signaling (Yu <i>et al.</i>, 2007; Blitzler and Nusse, 2006) - Dvl also binds β-arrestins (Seto and Bellen, 2006) - Complexes recruited to early endosomes - Formation of protein scaffolds required for signaling (Di Guglielmo <i>et al.</i>, 2003; Hayes <i>et al.</i>, 2002)
	TGF β receptor	TGF β	Phosphorylation of SMAD transcription factors and translocation to the nucleus	CME and requires FYVE protein SARA	- Alternative route of endocytosis – caveolin-dependent for receptor turnover and degradation - TGFβ receptor binding to SMAD7–Smurf2, recruitment of E3-ligase and ubiquitination of TGFβ are required for degradation (Di Guglielmo <i>et al.</i>, 2003)
	TGF β receptor	TGF β	TGF β receptor turnover	NCE (caveolin-mediated)	
Cytokine receptors	TNFR	TNF α	Caspase 8 activation in endosomes and TNF α apoptotic signaling	Endosomal PI3P and proteolytic enzymes	- Promotes assembly of the death complex in endosomes - In contrast to the survival signals initiated at the plasma membrane, TNFR signaling in endosomes induces cell death (Schneider-Brachert <i>et al.</i>, 2004; Liao <i>et al.</i>, 2008)
	TLR4	LPS	Switch from surface to endosome-specific signaling and induction of INF β gene.	Lack of PIP ₂ in endosomes	- Other TLR family members are found to reside mostly in endosomes where they detect viral nucleic acids (Kagan <i>et al.</i>, 2008) - Sustained endosomal TLR9 shown to be necessary for a potent type I INF response (Honda <i>et al.</i>, 2005)
Notch signaling	NOTCH	DSL	NOTCH cleavage and translocation to the nucleus	Low pH, γ -secretase and dynamin	γ-secretase is present in both endosomes and plasma membrane, however, peak activity is at low pH (Pasternak <i>et al.</i>, 2003) - NOTCH-DSL interaction is favored by low pH (Pei and Baker, 2008) - Endocytosis is necessary for cleavage of NOTCH (Vaccari <i>et al.</i>, 2008) - Role for dynamin in NOTCH endocytosis and <i>Drosophila</i> neurogenesis (Seugnet <i>et al.</i>, 1997)

(Continued)

Table 1 Continued

Receptor type	Receptor	Ligand	Proposed outcome of endosome signaling	Proposed requirements for signaling	Notes and references
	NOTCH	DSL	NOTCH signaling	Endocytosis of DSL on signal-sending cell	- Alternative models of NOTCH signaling involve endocytosis of its ligand DSL: - Endocytosis of DSL physically strips NOTCH extracellular domain to release NOTCH cytoplasmic domain for cleavage (Windler and Bilder, 2010) - Recycling of DSL is necessary for DSL activation and high plasma membrane concentration (Rajan <i>et al.</i>, 2009) – <i>Drosophila</i> - Posttranslational modifications, for example, mono-ubiquitination in signaling or recycling endosomes is required to activate ligands, for example, DSL (remains to be clarified) (Fortini, 2009)

Note: Signaling from endosomes is key for propagation and enhanced receptor signaling (light green rows), attenuation of receptor signaling (pink rows) or for a change in the receptor signaling outcome (pale yellow rows).

Abbreviations: APPL, adapter protein, phosphotyrosine interaction, PH domain and leucine zipper-containing; β 2AR, beta 2-adrenergic receptor; CME, clathrin-mediated endocytosis; DSL, *delta/serrate/lag* family; Dvl, disheveled; EEA1, early endosome antigen 1; EGF, epidermal growth factor; EGFR, EGF receptor; ERK, extracellular signal-regulated kinase; FYVE, zinc finger domain found in Fab1; YOTB/ZK632.12, Vac1, and EEA1; Fz1, frizzled; GPCR, G-protein–coupled receptor; HGF, hepatocyte growth factor; INF β , interferon beta; LPA, lysophosphatidic acid; LPS, lipopolysaccharide; LRP, low density lipoprotein receptor-related protein; MAPK, mitogen-activated protein kinase; Met, HGF receptor; NCE, non-clathrin-mediated endocytosis; NGF, neuronal growth factor; PDGF, platelet-derived growth factor; PDGFR, PDGF receptor; PI3K, phosphatidylinositol 3-kinase; PIP $_2$, phosphatidylinositol (4,5) bisphosphate; PLC- γ , phospholipase C-gamma; RTK, receptor tyrosine kinase; SARA, SMAD anchor for receptor activation; STAT3, signal transducer and activator of transcription 3; TGF, transforming growth factor; TGFR, TGF receptor; TLR, toll-like receptor; TNF α , tumor necrosis factor alpha; TNFR, TNF receptor; TrkA, neurotrophic tyrosine kinase receptor type 1; VEGF, vascular endothelial growth factor; VEGFR, VEGF receptor; Wnt, wingless-type MMTV integration site family member.

Figure 2 Different endocytosis routes lead to different biological outputs. EGFR and TGF β R can both be endocytosed via CME or NCE routes. Receptors endocytosed via CME are recycled back to the plasma membrane thus sustaining the signal, while receptors trafficked via the NCE route are directed to lysosomes for degradation. In the case of TGF β R, CME to EEA1 positive endosomes leads to receptor coupling with a SMAD anchor protein, SARA, which promotes TGF β R signaling from endosomes, whereas the caveolin-dependent internalization pathway leads to rapid receptor turnover.

Wnts constitute a large family of secreted ligands implicated in a wide array of developmental and physiological processes (Logan and Nusse, 2004; Yamamoto *et al.*, 2008). Wnt-induced low-density receptor-related protein 6 (LRP6) signaling results in NCE and relocalization of LRP6 to endosomes, where the Wnt-generated signal functions to stabilize β -catenin (Yamamoto *et al.*, 2008). In contrast, in response to Dickkopf family member 1 (Dkk1), a soluble ligand and a negative regulator of Wnt signaling, LRP6 undergoes CME and receptor degradation. In conclusion, the internalization routes of receptors can play a defining role on the signaling outcome upon ligand stimulation and interplay between different trafficking pathways facilitates fine-tuning of cellular signals.

Endocytosis Regulates Signal Termination and Cellular Response to Ligand Gradient

Ligand-induced endocytosis of RTKs is an important mechanism to downregulate cellular responsiveness to external stimuli. This may occur via sequestration of the receptor away from plasma membrane components that are critically important for signaling. For example, on the plasma membrane EGF-induced EGFR phosphorylation recruits SH2-domain containing lipid kinase PI3K or lipase phospholipase

C-gamma, that depend on plasma membrane enriched phospholipids as substrates. Following endocytosis the membrane lipid composition of endosomes no longer supports signaling by these molecules and results in signal termination (Haugh and Meyer, 2002).

Another important mechanism for endocytosis-regulated signal termination is lysosomal receptor degradation and subsequently reduced plasma membrane receptor levels. Lowered receptor levels can attenuate the overall signaling intensity within the cell but can also regulate cellular responsiveness in a localized and directional manner. An example of this localized receptor endocytosis and downregulation is demonstrated by the directionally migrating border cells during *Drosophila melanogaster* oogenesis (Jekely *et al.*, 2005; Duchek *et al.*, 2001). In this developmental process spatial localization of RTK signaling via EGFR and PVR (PDGF/vascular growth factor receptor) regulates directional cell migration. Receptor endocytosis is necessary in these cells to ensure a localized intracellular response to the growth factor-mediated guidance cues (Duchek *et al.*, 2001; Ducheka and Rorth, 2001). A similar mechanism is also involved in regulating cell migration within a growth factor gradient. Upon EGF stimulation the EGFR becomes sequestered at the advancing front of culture breast carcinoma cells. In this spatially restricted sub-cellular space endocytosis-mediated receptor downregulation gradually reduces cell responsiveness to chemotactic EGF and promotes directional cell migration (Bailly *et al.*, 2000; Figure 3).

Endosomes – A World of Their Own

What is special about endosomes? How are they capable of regulating specialized signaling events that are distinct from plasma membrane signals? What underlies their unique ability to allow vast diversification of signals within cells? As discussed above endosomes are capable of assembling novel signaling platforms, amplifying signals and differentiating between extended signaling and signal termination via degradation. Since the establishment of the signaling endosome concept several unique endosomal characteristics have been shown to contribute to endosome signaling. These unique physical characteristics of endosomes are: differential enrichment of membrane phosphoinositide phosphates (PIPs), the ability to recruit unique signaling adapter proteins, low acidic pH especially in the luminal compartment of late endosomes, high membrane curvature, confined size, and differential accessibility to cellular phosphatases (Figure 4).

PIPs

Endosomal membranes are enriched in phosphatidylinositol-3-phosphate (PI3P). This distinguishes them from the plasma membrane which is enriched in PI(4,5)P₂ (PIP₂) and PI(3,4,5)P₃ (PIP₃). In addition, the presence of PI3P defines different classes of endosomes by regulating the formation of endosome-specific signaling platforms. A population of early endosome precursors contain APPL1 and 2 (adapter protein, phosphotyrosine interaction, PH domain, and leucine zipper-containing) adapter proteins and lack PI3P. In the

Figure 3 Localized endocytosis regulates the distance and directionality of cell migration. Several plasma membrane receptors function as motogenic sensors allowing cells to respond and migrate toward an increasing concentration of a soluble chemoattractant and receptor endocytosis appears to be crucial for this process. For example, in an EGF gradient, EGFR is evenly distributed on the cell surface. However, the endocytosis of the ligand–receptor complex is polarized and occurs primarily at the leading edge of migrating cells where the EGF concentration is highest. The internalized receptors are guided for degradation thus reducing cell responsiveness to increasing levels of EGF, finally leading to a halt in cell migration.

Figure 4 The unique signal promoting features of endosomes. Endosomes have several special characteristics that enable them to regulate, modify, and sustain signaling. Endosomal membranes are rich in PI(3)P allowing the recruitment of several PI(3)P-binding domain (such as FYVE) containing proteins to endosomes. Endosomes also exhibit lower pH than the cell cytoplasm, which is needed for some proteases to function. In addition, endosomal membranes are inevitably more curved compared to the plasma membrane, allowing endosomes to recruit specific curvature-sensing proteins such as those containing a BAR-domain. Endosomes also enable receptors to escape from the action of plasma membrane phosphatases leading to sustained phosphorylation-dependent signaling and finally the compact size of endosomes can facilitate ligand–receptor interactions by increasing proximity of the molecules.

APPL-endosomes, APPLs interact with endosomal membranes directly, and through Rab5-guanosine triphosphate (GTP) association. They also interact directly or indirectly with active

RTKs. On very early endosomes APPLs are important for survival signaling along the Akt and glycogen synthase kinase 3 beta (GSK3 β) axis in zebrafish (Schenck *et al.*, 2008). However,

there appear to be context-dependent variations on the pathways regulated by APPL-endosomes. In zebrafish, Akt signaling to mammalian target of rapamycin (mTOR) occurs independently of APPLs whereas in cultured HeLa cells APPL-endosomes are implicated in activation of ERK1 and ERK2 as well as Akt signaling to both GSK3 β and mTOR (Zoncu *et al.*, 2009).

Maturation of APPL-endosomes to EEA1-containing early endosomes involves acquisition of PI3P through the recruitment of the class 3 PI3K. APPL and EEA1 compete for binding to Rab5-GTP on endosomes and the generation of PI3P shifts the balance in favor of EEA1 (Zoncu *et al.*, 2009). This so-called phosphoinositide-switch induces endosomal maturation and terminates APPL-dependent signaling from the endosomes. Released APPL can translocate to the nucleus where it regulates chromatin remodeling in conjunction with endosomal sorting complexes required for transport III (ESCRT-III) proteins (Stauffer *et al.*, 2001). Rab5 and EEA1 additionally recruit specific signaling complexes to early endosomes to determine signal specificity. For example, active Akt interacts with EEA1 and EEA1 endosomes are crucial for angiotensin-II-induced Akt activation and downstream signaling to mTOR and S6K, but not to ERK1/2 (Nazarewicz *et al.*, 2011).

A third class of early endosomes consists of the SARA-endosomes. SARA is an FYVE-domain containing adapter protein that localizes to a subset of PIP₃-containing endosomes. SARA binds directly to active TGF β R steering the receptor toward SARA-endosomes via CME. SARA recruits the TGF β R target SMAD2 to the same endosomal membrane and therefore promotes efficient phosphorylation of SMAD2 by TGF β R. This induces dissociation of SMAD2 from the endosomes and the formation of SMAD2–SMAD4 complexes that translocate to the nucleus to regulate transcription (Tsukazaki *et al.*, 1998).

Endosome Maturation and Unique Signaling Adapters

Different endosomal compartments are defined by specific Rab proteins. Rab5 is a small GTPase and an important signaling molecule characteristic to early endosomes and as described above regulates signaling specificity in endosomes. However, Rab5 is also involved in regulating the duration of endosomal signals. Endosome maturation involves a transition from Rab5 early endosomes to Rab7 late endosomes and results in a termination of Rab5-dependent signaling (Rink *et al.*, 2005). Activation of P38/mitogen-activated protein kinase (MAPK) induced by EGFR signaling, stress, or cytotoxic drugs promotes the formation of Rab5-GDI-EEA1 complexes and slows down the conversion of Rab5 to Rab7 endosomes resulting in accelerated EGFR endocytosis (Cavalli *et al.*, 2001; Zwang and Yarden, 2006; Sorkin and von Zastrow, 2009; von Zastrow and Sorkin, 2007). Thus, extended residency of receptors in Rab5 endosomes is linked to prolonged signaling.

Specific signaling platforms also exist on late endosomes and play a role in the ability of RTKs like EGFR to fully activate ERK1/2. On late endosomes, endosome-specific lipid-raft adapter protein p18 binds to a scaffold consisting of MAPK and ERK kinase 1 (MEK1), MEK1 partner (MP1) and p14, an adapter protein. Depending on the type of signaling system p14 and p18 are necessary for maintenance of basal MEK-ERK

activity or efficient MEK activation following EGF stimulation (Teis *et al.*, 2002, 2006; Nada *et al.*, 2009). In addition to RTK signaling, the late endosomal p14–MP1 complex is also important for K-Ras, but not H-Ras or N-Ras, signaling. Like other members of the Ras family, K-Ras is a GTPase and an early player in many signal transduction pathways. Active K-Ras is recruited to late endosomes where together with the p14–MP1 complex signals to Raf1 kinase following EGF stimulation (Lu *et al.*, 2009). Thus, endosomal maturation functions to specify signaling and facilitates assembly of signaling scaffolds found uniquely on late endosomes.

Low pH

As internalized materials progress through the endocytic pathway, they are exposed to an increasingly acidic pH. The pH of early endosomes is typically near 6, late endosomes near 5, and lysosomes exhibit even lower ranges. There are several ways by which the low endosomal pH can influence cellular signaling. EGF and TGF α are both EGFR ligands. EGF has a higher affinity for the receptor and is thus more likely to remain receptor-bound in endosomes inducing receptor targeting for lysosomal degradation. Conversely, TGF α dissociates from EGFR at an early stage of endocytosis in the mildly acidic environment of the early endosomes. This induces rapid recycling of the receptor and enables renewed receptor activation and signaling on the plasma membrane by the recycled receptor. Consequently, EGF but not TGF α induces receptor downregulation and this is reflected by the fact that TGF α is a much more potent mitogen than EGF (Waterman *et al.*, 1998). In the NOTCH pathway, plasma membrane cleavage of NOTCH results in endosomal localization of its transmembrane and intracellular domains. In the endosomes the NOTCH domains are further cleaved by a low pH-dependent protease, γ -secretase, functional only in late endosomes. This step is necessary for the nuclear localization of NOTCH to activate transcription (Vaccari *et al.*, 2008).

Confined Size

The luminal volume on endosomes is small and the limited size of the endosomes may help concentrate receptors and their ligands in a manner enabling continued receptor–ligand occupancy and thus sustained signaling from the endosome (Sorkin and von Zastrow, 2009). In addition, many of the protein–protein and protein–lipid interactions between endosomal small GTPases and their effectors, scaffolding proteins and signaling molecules are typically of low affinity. The limited surface area of an endosome is likely to favor and promote the assembly of such multi-protein complexes (Pawson, 2007; Scita and Di Fiore, 2010). Furthermore, proteins like APPLs have membrane curvature-sensing domains which may also enhance specific interactions with endosomal membranes.

Accessibility to Phosphatases

Signaling by activated RTKs can be effectively attenuated by protein tyrosine phosphatases (PTPs) (Mattila *et al.*, 2005) and internalization to signaling-competent endosomes may function to sequester receptors away from PTPs. In the case of

the Met-receptor, endocytosis prolongs signaling to STAT3, possibly due to reduced accessibility to plasma membrane phosphatases (Kermorgant and Parker, 2008). In T cells, signaling of Lck kinase in endosomes is counteracted by CD45 phosphatase (Danielian *et al.*, 1992). However, at present it is not known whether CD45 is excluded from these endosomes. On the other hand, phosphatases can promote endosomal signaling. Endosomally localized PP2A serine-threonine phosphatase is essential for resensitization of G-protein-coupled receptor (GPCR) signaling enabling relocalization of the receptor to the plasma membrane in a functional form (Scita and Di Fiore, 2010). Additionally, a role for phosphatases in endosome regulation has been described downstream of the Ephrin B receptor. Activation of this receptor leads to the phosphorylation of synaptojanin, a phosphatidylinositol-5-phosphatase involved in uncoating of clathrin-coated vesicles following internalization, resulting in a subsequent decrease in phosphatase activity that influences the CME of the transferrin receptor and α -Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) glutamate receptor (Irie *et al.*, 2005). Synaptojanin is also believed to be preferentially recruited to curved endosome membranes by interacting with BAR-domain proteins. This specific recruitment of synaptojanin promotes removal of PIP₂ (Chang-Ileto *et al.*, 2011) and therefore provides a differential phospholipid environment for protein interaction or chemical reactions.

Endocytosis Regulates Spatial Signaling and Signal Amplification

As described above, several RTKs and GPCRs remain in their ligand-bound active state after internalization in endosomes, thus enabling sustained receptor signaling. The relatively long residence time in endosomes compared to the generally fast internalization step from the plasma membrane allow signal amplification and ensure sufficient intensity of signaling. On the other hand, endosomes can protect phosphorylated receptor/protein signals from cytoplasmic phosphatases by transporting the membrane-associated signaling molecules rapidly inside the cell via directional microtubules. This concept was elegantly demonstrated in a mathematical model of transcription factor STAT3 signaling first presented by Howe (2005). STAT3 is activated by phosphorylation following engagement of different receptors at the plasma membrane after which STAT3 needs to be translocated into the nucleus. In the mathematical model, Howe compared a random diffusion of phosphorylated STAT3, combined with probabilistic modeling of dephosphorylation kinetics, to a direct membrane-associated microtubule-guided transportation system from the plasma membrane to the nucleus. Based on this model, if the distance traveled by phosphorylated signaling proteins exceeds 200 nm, the endosomal transport system along microtubules is more efficient and less information is lost due to dephosphorylation compared to a random diffusion (Howe, 2005).

In some cases, however, the signaling intensity is sufficiently high enough to reach the required threshold so that a simple diffusion through a phosphatase-rich cytoplasm can in fact be sufficient to relocate active signaling proteins to the nucleus. For example, in the case of STAT3, the efficiency and

amplitude of STAT3 activation seems to be receptor dependent. Cytokine oncostatin-M activates STAT3 from the plasma membrane after which STAT translocates to the nucleus by classical diffusion. However, the hepatocyte growth factor (HGF)-induced Met-receptor generated STAT-signal is weaker and thus the activated receptor itself needs to be transported by endocytosis closer to the nucleus to reach the same threshold of signaling and lead to nuclear accumulation of STAT3. Yet this is not the case for all Met signaling events as HGF-Met-induced nuclear accumulation of MAPK does not require perinuclear Met localization, although endocytosis is needed for full ERK1/2 activation.

A classic example of sustained and spatially regulated signaling mediated by endocytosis is the signaling of neurotrophin receptors. As already described earlier in this article, NGF-induced TrkA receptors need to transmit signals from nerve terminals to the nucleus over long distances (which can easily reach a meter). This would of course not be possible with random diffusion in a limited time and is only accomplished by endosomal transportation of the receptor–ligand complexes, thus sustaining the receptor-mediated ERK1/2 and PI3K/Akt signaling over long distances. Spatial restriction of signals is also critical for actin remodeling and thus for cell migration and invasion. Rac GTPase, an important signaling molecule involved in actin reorganization, has been shown to be activated on early endosomes after Rab5-mediated endocytosis. Activated Rac is then recycled to specific locations at the plasma membrane to provide localized signaling leading to actin polymerization-driven membrane protrusion and finally to increased cell migration and invasion (Palamidessi *et al.*, 2008).

An intriguing example of the importance of endocytosis in defining signaling outcome is described for the death receptor tumor necrosis factor receptor 1 (TNFR1). Ligand-induced activation of TNFR1 on the plasma membrane induces anti-apoptotic signals by activating the nuclear factor kappa B (NF- κ B) leading to cell protection. However, receptor internalization via CME leads to the recruitment of the ‘death-inducing signaling complex’ followed by termination of NF- κ B signaling that ultimately leads to apoptosis. In conclusion, the same receptor–ligand complex can induce both pro- and anti-apoptotic signaling, depending solely on the subcellular location (Schneider-Brachert *et al.*, 2004; Schutze *et al.*, 2008).

Signaling Regulates Endocytosis

The examples discussed so far highlight the important role of endosomes and endocytic pathways in determining the outcome of a membrane receptor-initiated signal. However, there is an extensive and reciprocal relationship between endocytosis and plasma membrane-derived signaling events. Indeed, accumulating evidence suggests that receptor-initiated signals can control endocytosis through the activation of pathways that impinge on endosome formation and maturation and on the route of internalization.

Transcription and Phosphorylation

Signals that control transcriptional programs represent the earliest stage at which endocytosis may be regulated.

For example, activation of hypoxia-induced transcription factor 1 α (HIF1 α) delays early endosome maturation by inhibiting Rabaptin-5 transcription (a Rab5 GTPase effector) leading to endosome retention of EGFR and sustained signaling (Wang *et al.*, 2009; Zhong *et al.*, 1999). Stress signals can also activate the tumor suppressor transcription factor p53 (TP53) resulting in suppressed cell growth through the regulation of many genes. In terms of endocytosis, TP53 activation mediates transcription of an ESCRT-II complex subunit, a lysosomal membrane protein and caveolin-1 resulting in simultaneous internalization of caveolin-1 and EGFR to multivesicular bodies to inhibit EGFR signaling and cell growth during stress conditions (Yu *et al.*, 2009).

Phosphorylation-dependent regulation of endocytosis can occur at several stages of endocytosis to influence the uptake of receptors and the formation and maturation of endosomes. Ligand-induced CME is usually dependent on receptor activation and autophosphorylation of specific residues within the receptor to recruit downstream effectors. In addition, ligand-induced activation of receptors, such as EGFR or TrkA, has been shown to trigger a rapid increase in the number and density of plasma membrane-associated CCPs that is dependent on Src kinase phosphorylation of the clathrin heavy chains and assembly of the clathrin triskelion (Wilde *et al.*, 1999; Beattie *et al.*, 2000; Sorkin and von Zastrow, 2009), clearly demonstrating that ligand-triggered signaling can initiate endocytosis.

The link between signaling and endocytosis has been investigated further in comprehensive RNA interference (RNAi) screens. In 2005, Pelkmans *et al.* revealed a role for a number of kinases in endocytosis in human culture cells. Interestingly, several kinases produced opposing effects on CME of the transferrin receptor and NCE of virus suggesting that distinct pathways can be coordinated by the same kinase (Pelkmans and Zerial, 2005). More recently, a genome-wide RNAi screen revealed that there is extensive cross talk between different molecular systems such that the components of signaling pathways including Wnt, integrins, TGF β , and NOTCH appear to regulate the endocytosis of other plasma membrane-derived signals including transferrin and EGF at different levels (Collinet *et al.*, 2010).

Actin in Regulation of Endocytosis – Actin Adapters, Stabilization of Tubules, and Vesicle Motility

The spatial and dynamic regulation of actin assembly and polymerization occurs downstream of several signaling events, including cell adhesion and RTK activation, and is fundamental for determining cell shape and the mode of cell migration. Tight regulation of actin dynamics is in turn crucial for several forms of cellular uptake, including phagocytosis, macropinocytosis, and some cases of NCE. Much of the early discussions for a role of actin in CME endocytosis have stemmed from studies in yeast demonstrating a complete dependency on actin dynamics for generation of membrane curvature, stabilization of endocytic vesicles, and vesicular scission. While it is apparent that this is not the case in mammalian cells where actin is dispensable for endocytosis, nevertheless an important regulatory role for actin in mediating endocytosis in mammalian cells has become evident. In

particular, live-cell imaging has revealed that several actin-binding/regulatory proteins are recruited to CCP (Sigismund *et al.*, 2012; Merrifield *et al.*, 2005; Yarar *et al.*, 2005) prior to detachment of the vesicles from the plasma membrane. In addition, several mammalian proteins have been shown to directly link endocytic pathways to the actin cytoskeleton. For example: dynamin, a GTPase involved in vesicle fission, binds directly to cortactin, an actin-related protein 2/3 (ARP2/3) activator and inducer of actin polymerization (Kessels *et al.*, 2001; McNiven *et al.*, 2000), HIP1R, a component of CCPs binds actin and cortactin (Le Clainche *et al.*, 2007) and intersectin binds to N-WASP to promote actin nucleation and facilitate CME (Hussain *et al.*, 2001). These interactions may serve to couple cellular processes that lead to extensive actin remodeling and cellular reorganization – such as changes in cell shape during cell migration – to the tight regulation of the endocytic pathway.

The requirement for actin in endocytosis has been further demonstrated in specific cell types. In neuronal cells, proteomic analysis of TrkA signaling endosomes revealed an association of TrkA complexes with actin-modulatory proteins such as cofilin. Importantly, cofilin-mediated dissociation of actin, in distal axons, was shown to be essential for NGF-stimulated retrograde transport of TrkA endosomes and thus potentiation of survival signals (Harrington *et al.*, 2011). Another study has highlighted the requirement for actin in stabilizing the formation of endosomal tubules and for concentrating B2AR (a GPCR) in these tubules for differential sorting (Puthenveedu *et al.*, 2010). Actin is further involved in both yeast and mammalian cells in endosome motility where actin, together with microtubules forms a crucial component of the transport machinery driving vesicular traffic (Ross *et al.*, 2008).

The examples described here are only a subset of the signaling pathways that regulate endocytosis. The reciprocal nature of regulation between signaling and the endocytic machinery is very complex and is crucial for constraining biological activities within cells that may otherwise lead to disease.

Endocytosis and Implications in Cancer

Considering the vast number of signaling pathways influenced by endocytosis and endosome signaling it is perhaps not surprising to find alterations in endocytic proteins and regulators in many human diseases. An interesting and comprehensive summary of altered endocytic proteins in human disease can be found in Sigismund *et al.*, 2012.

Increasing evidence also supports a role for the endocytic machinery, in particular endosome signaling, in cancer progression. For example, tumor hypoxia and HIF1 α overexpression, which has been shown to sustain endosomal EGFR signaling, are associated with aggressive tumor progression and poor prognosis in patients (Sigismund *et al.*, 2012; Wang *et al.*, 2009; Zhong *et al.*, 1999) and endosomal localization of EGFR appears to confer drug resistance to therapeutic antibodies (Nevo *et al.*, 2009).

Endocytosis also regulates several other oncogenic RTK signaling pathways. Met RTK and its ligand HGF are frequently

overexpressed in human cancer resulting in hyperactivation of the pathway and induction of cell functions such as proliferation, migration, and survival. Activated Met is rapidly internalized and continues to signal from endosomal compartments prior to degradation. Importantly, Met signaling from endosomes has recently been shown to be involved in tumorigenesis and endocytosis appears to be critical for active Met mutants to trigger anchorage-independent growth, transformation, and metastasis (Joffe *et al.*, 2011). In addition to RTK signaling, endocytosis is required for: activation of other oncogenic receptors (e.g., NOTCH) (Furthauer and Gonzalez-Gaitan, 2009), trafficking of key adhesion receptors (e.g., integrins) to regulate cell proliferation, cell migration, and cell survival and for spatial restriction of signals involved in cell migration (e.g., Rho GTPase signaling) (Caswell and Norman, 2008; Sigismund *et al.*, 2012).

These signaling and trafficking events are often misregulated in cancer and contribute to a highly motile and invasive cell phenotype. Additionally, there is now mounting evidence for a more direct role of endocytic proteins or regulators in human tumors (Mosesson *et al.*, 2008; Lanzetti and Di Fiore, 2008).

Conclusions and Future Perspectives

Joint efforts from cell biologists, molecular biologists, biochemists, and developmental biologists have firmly established the concept of signaling endosomes and demonstrated the functional relevance of endosome-derived signal transduction in a wide range of biological systems. Nevertheless, compared to the large body of work devoted to plasma membrane signaling our knowledge of endosomal signaling still remains rather underdeveloped. Distinguishing between plasma membrane and endosomal signals is challenging and requires careful experimental set up. Hopefully, future advances in techniques such as quantitative proteomics, improved cell fractionation protocols and use of specific kinase inhibitors to restrict signaling post-endocytosis will facilitate research in this field. RTKs and other cell surface receptors are the focus for designing targeted therapies for many human diseases including cancer. An in-depth understanding of the entire signaling system from the plasma membrane to the endosomes and lysosomes will be a key for the success of these translational efforts. Furthermore, as with any signaling pathway in cells, endosomal signaling appears to be highly context-dependent and is most likely intimately linked to adhesion, the cytoskeleton and micro environmental cues sensed by the cells. This is a largely unexplored area in endosomal signaling and increasing our understanding in this area will require joint efforts from different fields of biology.

Conventional and Secretory Lysosomes

Introduction

Lysosomes were first described by Dr. Christian de Duve in 1955 as the major degradative compartment within eukaryotic cells (Appelmans *et al.*, 1955; de Duve, 1959). Structurally they appear as dense bodies that often are found associated with the microtubule-organizing center (MTOC) near the nucleus of the cell. They can vary in size, shape, and number depending upon the cell type. Recently, the quantity of lysosomes was found to be regulated by the transcription factor EB (TFEB) (Sardiello *et al.*, 2009). TFEB recognizes a DNA sequence (GTCACGTGAC) termed coordinated lysosomal expression and regulation or CLEAR sequence found in many genes that encode for lysosomal proteins (Settembre *et al.*, 2013). TFEB controls the biogenesis of lysosomal hydrolases and membrane proteins. It exists in the cytosol and under altered lysosomal conditions such as nutrient starvation or hyperaccumulation of substrates, TFEB translocates to the nucleus to activate lysosome biogenesis gene transcription, thus generating increased numbers of lysosomes. Lysosomes possess an acidic lumen containing many types of hydrolases responsible for the degradation of substrates. The high H⁺ content is driven by the presence of the vacuolar ATPase H⁺ pump. Lysosomes also contain high levels of calcium (Ghislat and Knecht, 2013), second in amount compared to the ER. The lysosomal membrane contains highly glycosylated proteins including lysosome-associated membrane proteins (LAMPs) and lysosomal integral membrane proteins (LIMPs). This high level of glycosylation is thought to protect the proteins from the degradative enzymes stored in lysosomes. Cytosolic facing lysosomal proteins are involved in regulating the transport of material to and from the lysosome (Safitig and Klumperman, 2009; Luzio *et al.*, 2014). Transport to the lysosome is primarily achieved through vesicular delivery of endocytosed or phagocytosed material. Along this delivery pathway to the lysosome lipids and proteins can be recycled from endosomal compartments or they can be targeted to lysosomes for degradation. Lysosomes can also obtain cytosolic components such as proteins, lipids, and organelles destined for degradation through regulated autophagy (Schneider and Cuervo, 2014; Parzych and Klionsky, 2014). The digestive nature of lysosomes allows for the reuse of amino acids and lipids as building 'material' for generating new nucleic acids, proteins, lipids, and organelles.

Along with their degradative functions, specialized lysosomes termed lysosome-related organelles (LROs) or secretory lysosomes can be found in most cells types. Examples of secretory lysosomes include melanosomes, lytic granules, platelet dense granules, and major histocompatibility complex class II (MHCII) compartments. They share many properties of lysosomes but also have cell-specific functions such as pigmentation, host defense, coagulation, and innate and adaptive immunity. This review will focus on the characteristics of lysosomes and cell-specific secretory lysosomes, their biogenesis

and functions including an emphasis on the importance of conventional and secretory lysosomes in human disease.

Conventional Lysosomes

All eukaryotes possess organelles that are ascribed to have lysosomal functions, the storage, and degradation of molecules. In plants and fungi such as the model organism *Saccharomyces cerevisiae*, lysosomes are called vacuoles. Much of what is known about lysosome biogenesis and delivery to lysosomes can be attributed to the exquisite genetic studies done in yeast (Schekman, 1985; Rothman *et al.*, 1989; Klionsky *et al.*, 1990; Bryant and Stevens, 1998; Wickner, 2010; Wickner and Haas, 2000; Efe *et al.*, 2005). Historically, the lysosomal compartment has been considered to be an endpoint organelle and many reviews on the endocytic system still depict this organelle as an endpoint. Over the past 20 years it has been appreciated that this organelle is not the endpoint of the endocytic pathway but rather is another membrane compartment where sorting occurs, pathogens can be degraded or persist, signaling can be initiated and energy metabolism can be assessed (Luzio *et al.*, 2014; Borlace *et al.*, 2011; Barrias *et al.*, 2013; Baxt *et al.*, 2013; Settembre *et al.*, 2013). Lysosomes and secretory lysosomes can be distinguished from late endosomes by the absence of mannose-6-phosphate receptors (M6PR) (Brown *et al.*, 1986), receptors responsible for the delivery of lysosomal hydrolases to the developing lysosome. The delivery of molecules to lysosomes can be mediated either by transport vesicles from the trans-Golgi network (TGN) fusing with late endosomes followed by the recycling of components required for further rounds of delivery from the TGN or by direct delivery of LAMPs from the TGN to lysosomes through an adaptor protein (AP). This AP-mediated delivery provides a mechanism for coated vesicles to sort cargo specific for lysosomal delivery. The delivery of molecules from late endosomes to lysosome was coined 'kiss-and-run,' in which late endosomes briefly fuse with lysosomes forming a hybrid organelle that fissions reforming lysosomes and recycling late endocytic vesicles (Bright *et al.*, 1997; Luzio *et al.*, 2007; Luzio *et al.*, 2005; Luzio *et al.*, 2000; Mullock *et al.*, 1998). Biochemical and microscopic evidence has also shown that lysosomes are capable of fusing with other lysosomes (homotypic fusion) and they can subsequently fission (Patterson and Lippincott-Schwartz, 2002; Ward *et al.*, 1997; Ward *et al.*, 2000; Durchfort *et al.*, 2012; Perou *et al.*, 1997; Michailat *et al.*, 2012; Michailat and Mayer, 2013; Peters *et al.*, 2004; Zieger and Mayer, 2012; Schulze *et al.*, 2013). This dynamic nature allows for the redistribution of substrates among lysosomes for efficient degradation and regulates the size of the lysosomes.

Cell Type-Specific Secretory Lysosomes

Secretory lysosomes are a subset of organelles that are indistinguishable from lysosomes, or they can be a distinct subset

of organelles that are present in cells that also contain 'traditional' lysosomes. The function of these LROs varies depending upon the cell type. Most cell types contain secretory lysosomes involved in plasma membrane repair (Jaiswal *et al.*, 2002; Bansal *et al.*, 2003; Keefe *et al.*, 2005; Zhang *et al.*, 2007; Laulagnier *et al.*, 2011; Xu *et al.*, 2012a; McNeil, 2002; McNeil and Kirchhausen, 2005). Plasma membrane injury can occur due to mechanical stress (e.g., muscle, skin, endothelial cells, and adipocytes) or by pathogens trying to gain access to host cells (e.g., pore-forming toxins generated by bacteria). Scientists have taken advantage of plasma membrane repair mechanisms to introduce reagents (DNA, immunoglobulins, and drugs) into cells by electroporation, glass-bead disruption, or scrape-loading methods. The repair of the plasma membrane occurs within seconds/minutes and is essential for survival. This process involves the influx of calcium, which binds to the phospholipid-binding protein synaptotagmin VII (Andrews *et al.*, 2014), triggering interaction with soluble N-ethylmaleimide-sensitive factor (NSF) attachment protein receptors (SNAREs) such as SNAP-23, which are necessary for membrane fusion and cytoskeletal rearrangement. The fusion of lysosomes at the wound site results in lysosomal hydrolases being released extracellularly and the presence of lysosomal membrane proteins including LAMPs, LIMPs and the vacuolar H^+ -ATPase localized at the cell surface. A lysosomal enzyme, acid sphingomyelinase, has been shown to be important for the restoration of plasma membrane integrity (Tam *et al.*, 2010). Data suggest that the transient plasma membrane localization of the vacuolar H^+ -ATPase may provide the necessary pH conditions for acid sphingomyelinase to function at the outer leaflet of the plasma membrane generating ceramide (Xu *et al.*, 2012b), which produces an inward bulging of the plasma membrane and the dynamin-independent internalization of the wound repair site (Idone *et al.*, 2008; Lariccia *et al.*, 2011; Sinha *et al.*, 2011; Jiang and Chen, 2009). The endocytosis of the wound patch allows for the recovery of the lysosomal membrane proteins. Defects in plasma membrane repair are associated with a broad range of human diseases including neurodegeneration, muscular dystrophy, lysosomal storage diseases (LSDs), heart disease, skin disorders, and obesity.

Hematopoietic-Lineage Secretory Lysosomes

Distinct subsets of secretory lysosomes are found in the cells that belong to hematopoietic lineages such as lymphocytes, granulocytes (eosinophils, neutrophils, basophils, mast cells), platelets, and macrophages. These vesicles contain cell type-specific molecules that are involved in disease-related processes including pathogen killing, lysing virally or bacterially infected cells and lysing tumourigenic cells. The secretory lysosomes are also involved in homeostatic processes including promoting coagulation and antigen presentation in innate and adaptive immune responses.

In cytotoxic T lymphocytes (CTLs), the LROs or lytic granules are the only lysosomes present in the cells. They store acid hydrolases to degrade endocytosed material but also contain secretory molecules such as perforin and granzymes, which function at neutral pH to insert into target cell

membranes at the immunologic synapse forming a pore that can result in target cell killing (Holt *et al.*, 2006; Luzio *et al.*, 2007; Pattu *et al.*, 2013; Figure 1). Another important molecule contained in small vesicles within these secretory lysosomes is Fas ligand (FasL), a transmembrane protein that is released in small vesicles when the lysosomes fuse with the plasma membrane at the immunologic synapse (Zuccato *et al.*, 2007). The small vesicles then fuse with the target antigen-presenting cell that contains Fas and this recognition triggers apoptosis. Loss of FasL gives rise to autoimmune lymphoproliferative syndrome or ALPS1B (Wu *et al.*, 1996). The release of the lytic granule contents at the immunologic synapse provides a restricted 'barrier' to protect against unwanted killing of neighboring cells.

Some of the mechanisms for lytic granule release have been elucidated through the use of inhibitory molecules (e.g., microtubule depolymerizing agents such as nocodazole or nonhydrolyzable nucleotides (GTP γ S or ATP γ S) and through the identification of human mutations in genes encoding required components. Two such components are the ras-related small GTPase (Rab) Rab27a, which is required for docking of the lytic granule at the plasma membrane, and Munc13-4, which is an effector molecule of Rab27a that regulates fusion with the plasma membrane. Mutations in the genes that encode Rab27a (Menasche *et al.*, 2000; Desnos *et al.*, 2003; Menasche *et al.*, 2003) or Munc13-4 (Feldmann *et al.*, 2003; Yamamoto *et al.*, 2004; Garrett *et al.*, 2012) result in defective cytotoxic T cell killing and human diseases (Griscelli syndrome and hemophagocytic lymphohistiocytosis, respectively). Several SNARE molecules (proteins on cognate donor and acceptor membranes that act as addressing molecules) required for lytic granule exocytosis in CTLs include Vamp8 (Loo *et al.*, 2009), Vti1b (Dressel *et al.*, 2010), Syntaxin7 (Pattu *et al.*, 2011), Syntaxin11 (Bryceson *et al.*, 2007; Halimani *et al.*, 2014), Munc18-2, and Synaptobrevin2 (Matti *et al.*, 2013). Mutations in many of these genes in humans give rise to type 3-5 familial hemophagocytic lymphohistiocytosis (FHL), a life-threatening disease where the immune system produces too many activated immune cells that can damage major organs of the body (Faitelson and Grunebaum, 2014; Sieni *et al.*, 2014). Similar regulatory mechanisms for LRO secretion appear to exist in natural killer (NK) cells although NK cells also have nonsecretory lysosomes that function to degrade endocytosed material (van der Sluijs *et al.*, 2013).

Neutrophils contain primary and secondary granules (LROs) that assist in the uptake and killing of bacteria. During phagosome formation the cell undergoes a change in the localization of the MTOC toward the forming phagosome (Tapper *et al.*, 2002). The primary granules can fuse with the phagosomal membrane and release of granule content assists in bacterial killing. The contents of the granules are very specific. Primary or azurophilic granules contain proteases such as elastase, Cathepsin G, antimicrobial peptides, and myeloperoxidase. Secondary granules contain lactoferrin and lysozyme, which are directed, respectively, at limiting bacterial iron acquisition and lysis of pathogen cell walls.

Basophils and mast cells have secretory lysosomes that act in inflammation often associated with allergic reactions. They contain acid hydrolases along with various inflammatory mediators such as histamine, heparin, serotonin, and neutral

Figure 1 A model of the immunologic synapse in cytotoxic T lymphocytes (CTLs) secretory lysosome release. T-cell receptors on CTL recognizes antigen on antigen presenting cell in the context of MHC forming the immunologic synapse. This recognition sends a signal that causes the CTL centromere to polarize toward the immunologic synapse. Secretory lysosomes engage the microtubule machinery to move them toward the plasma membrane at the immunologic synapse. These lytic granules contain Fas ligand (FasL) that recognizes Fas being expressed on the antigen presenting cell. They also contain the pore-forming protein perforin and granzymes, which upon release at the synapse form a pore in the plasma membrane that induces apoptosis of the antigen presenting cell. Included is a list of known regulator of CTL secretory lysosome fusion.

proteases (Marone *et al.*, 1997). Eosinophilic secretory lysosomes are associated with host defense against parasitic helminthes, allergic reactions, and immunoregulation. The granules contain a variety of molecules including cationic proteins, growth factors, cytokines, receptors, and lytic molecules. The selective sorting of these molecules into eosinophil granules as well as their regulated release has identified different mechanisms that mediate release of granule contents (Muniz *et al.*, 2012). These mechanisms include: (1) compound exocytosis where the entire granule fuses with the plasma releasing its contents to kill target cells or parasites; (2) selective secretion of specific contents through tubular/vesicular structures that are released from the secretory lysosomes and fuse with the plasma membrane to release their contents; and (3) whole cell eosinophil lysis, which releases intact granules that may be directed to target cells or pathogens via membrane recognition molecules.

Macrophages contain conventional lysosomes as well as secretory lysosomes that are involved in membrane repair, pathogen killing, and immunomodulation. Specialized macrophages such as osteoclasts utilize these secretory

lysosomes to deliver acid hydrolases to sites of bone resorption (Teitelbaum, 2000). These secretory lysosomes contain a subset of acid hydrolases including cathepsin K and tartrate-resistant acid phosphatase or TRAP, two enzymes that play a role in bone resorption, which is critical for skeletal formation and remodeling (van Meel *et al.*, 2011). Some of the molecules that have been implicated in the release of secretory lysosomes in osteoclasts include Synaptotagmin VII (Zhao *et al.*, 2008), Syntaxin4, and Rab7 (Zhao *et al.*, 2001).

The megakaryocyte, the platelet-forming cell, contains secretory and conventional lysosomes. Platelets, which are only found in mammals, are formed by the shedding or breaking off of fragments of the megakaryocyte into the bloodstream. Platelets contain three kinds of secretory lysosomes: dense core granules containing clotting factors (fibrinogen, Von Willebrand Factor, and nucleotides), alpha granules containing vasoconstricting factors (serotonin and calcium), and lysosomes containing acid hydrolases and clot remodeling factors (plasminogen activator inhibitor-1 (PAI-1) and thrombin activatable fibrinolysis inhibitor (TAFI)) (Flaumenhaft *et al.*, 2009, Italiano *et al.*, 2008). These secretory lysosomes can also

release a number of chemokines and cytokines, which promote activation of leukocytes for immune response (Ren *et al.*, 2008). Secretory lysosomes must be moved to the periphery of the megakaryocyte prior to shedding of platelets. A failure to appropriately move vesicles will result in coagulation defects, which is a common phenotype associated with human diseases such as Chediak–Higashi syndrome (CHS), Hermansky–Pudlak syndrome (HPS), Gray Platelet syndrome (GPS), and Griscelli's syndrome (GS). Some details of these human diseases associated with secretory lysosome defects will be described later in this article. The basic machinery that moves and fuses vesicles with the plasma membrane is conserved for all secretory lysosome release, however, there are cell type-specific molecules that mediate this process. Molecules required for platelet dense granule release have been characterized through human disease gene identification, mouse knockouts and platelet dense granule proteomics (Lemons *et al.*, 1997; Flaumenhaft *et al.*, 1999; Chen *et al.*, 2000; Lemons *et al.*, 2000; Reed, 2004; Ren *et al.*, 2008). More recently syntaxin-binding protein 5 was shown to bind to core secretion machinery regulating when and where SNARE interactions occur, and the knockout mouse showed defective hemostasis and bleeding tendencies (Ye *et al.*, 2014). The general mechanisms of secretory lysosome fusion are discussed in detail below.

Nonhematologic Cell Secretory Lysosomes

While the specialization of secretory lysosomes is most pronounced in hematopoietic cell lineages, all cells have secretory lysosomes. The endothelial cell contains specialized secretory lysosomes termed Weibel–Palade bodies (Weibel and Palade, 1964), which play a key role in wound repair and coagulation (Hannah *et al.*, 2002). These secretory vesicles contain von Willebrand factor that is important in blood clotting (Sakariassen *et al.*, 1979; Ewenstein *et al.*, 1987; Ruggeri, 1999), as well as the membrane protein P-selectin (Bonfanti *et al.*, 1989; McEver *et al.*, 1989), which recruits leukocytes that play a role in initiating inflammation (Dore *et al.*, 1993; Mayadas *et al.*, 1993; Nolte *et al.*, 1994).

Astrocytes, neurons, and pulmonary type II cells have also been shown to contain specialized secretory lysosomes (Zhang *et al.*, 2007; Tribl *et al.*, 2006; Weaver *et al.*, 2002) that function in ATP, pigment and surfactant storage and regulated release.

The discovery that melanosomes are secretory lysosomes in pigment cells has provided much of the basis for understanding basic LRO biogenesis and plasma membrane release. This work was initiated by the observation that there were human diseases associated with pigmentation defects and that affected individuals often showed defects in hemostasis and immune function. Along with the more detailed characterization of these human diseases, mouse geneticists noticed that several spontaneously occurring mouse strains possessed varying levels of coat color defects and those mice often showed defects in other secretory lysosome functions (Jackson, 1991). The combination of these two observations provided the tools to identify those genes responsible for pigmentation and the biochemical pathways regulating LRO formation, movement, and function. During their development, melanosomes contain the enzymes and scaffolding proteins along

with several ion channels necessary for the synthesis of complex pigments. These pigments provide photoprotection from ionizing radiation and regulate retinal function in the eye (Raposo and Marks, 2007). The biogenesis of these organelles follows a highly specialized endocytic trafficking pathway (Wu and Hammer, 2014), which is more specifically detailed in the article on LROs.

Biogenesis of Lysosomes and Secretory Lysosomes

The generation of secretory lysosomes follows the same pathway as lysosome biogenesis. The delivery of internalized membrane, through endocytosis provides a pathway for selective sorting. Endosomes proceed through a series of sorting events where receptors and other plasma membrane components are recycled (e.g., transferrin receptor) as the endosome is 'matured.' Cargo destined for degradation remains in the endosome. The maturing endosome invaginates to form the multivesicular body (MVB) through a series of specific protein recruitment events that are regulated by the endosomal sorting complexes required for transport (ESCRT)-dependent machinery. Ubiquitin 'marked' membrane proteins are sorted into intraluminal vesicles that will be delivered to the lysosome for degradation. Again, much of this work was initially done in *S. cerevisiae* (Babst *et al.*, 2002a; Babst *et al.*, 2002b; Katzmann *et al.*, 2001; Babst and Odorizzi, 2013; Henne *et al.*, 2013), but a great deal of the knowledge on the mechanisms involved in MVB formation has come about through the study of virus release, specifically human immunodeficiency virus (HIV) (Votteler and Sundquist, 2013) and cell abscission (Carlton and Martin-Serrano, 2007; Morita *et al.*, 2007). There are currently over 20 ESCRT proteins in mammals and their roles in MVB formation, sorting, and trafficking and other cellular process such as abscission and exosome release are still being defined (McCullough *et al.*, 2013; Schuh and Audhya, 2014).

Hydrolases and other soluble lysosomal components, synthesized in the ER and trafficked through the Golgi for additional glycosylation, can be delivered to the now late endosome through M6PR, which release their cargo upon exposure to the acidic environment of the forming lysosome (Fischer *et al.*, 1980; Kornfeld and Mellman, 1989; Braulke and Bonifacino, 2009; Saftig and Klumperman, 2009). Other delivery mechanisms independent of M6PR are known to exist, as hydrolases can be delivered to lysosomes in the absence of M6P glycosylation as in the human disorder I-cell disease due to a deficiency in N-acetylglucosamine-phosphotransferase (Coutinho *et al.*, 2012). Membrane proteins destined for residence in lysosomes contain targeting motifs, YXX ϕ or [DE] XXXL[LI], which are recognized by adaptor proteins (AP) that sort them into coated cargo vesicles for delivery with the late endocytic machinery (Park and Guo, 2014). This can occur in the biosynthetic pathway via AP1 or AP3 or via an indirect route to the plasma membrane where the adaptor protein AP2 assists in the recognition and endocytosis of lysosomal proteins. There is also evidence that lysosomal membrane proteins such as LAMP1 and LAMP2 can be delivered to the forming lysosome in an AP-independent M6PR-independent manner (Pols *et al.*, 2013).

The mechanisms for sorting to conventional lysosomes also provide for the sorting of molecules to secretory lysosomes. There are some specialized sorting mechanisms in CTL secretory lysosome biogenesis that involve ubiquitination and phosphorylation of FasL and trafficking through the MVB for delivery to LROs (Park and Guo, 2014). Consistent with cell type-specific secretory lysosome sorting is the trafficking of elastase into neutrophils through the tetraspanin molecule CD63 (Harrison-Lavoie *et al.*, 2006). The sorting of molecules into the forming melanosomes is highly specific for melanocytes and deviates from typical secretory lysosome formation by sorting from the early rather than late endosomal compartment and there are no internal vesicles (Marks *et al.*, 2013).

Exocytosis of Secretory Lysosomes

The regulated secretion of LROs has some general principles that apply to all cell types (Figure 2). The first step in secretion is signaling to the cell to release secretory lysosomes. This

signal can be the influx of calcium as in wound repair or it may be a receptor ligand signal as in CTLs or NK cells where the formation of the immunologic synapse (TCR-antigen-MHC) signals the polarization of the cell and the movement or localization of 'mature' secretory lysosomes near the plasma membrane, however, not all cells polarize to release secretory lysosome contents. Secretion requires binding of the secretory lysosome to microtubules through the kinesin family of motor proteins providing long distance movements toward the cell periphery. The secretory lysosome is then released and may bind to actin through myosin motors for more subtle movements close to the plasma membrane. Once the secretory lysosome is near the plasma membrane docking molecules on the secretory lysosome and plasma membrane tether the vesicle to the plasma membrane. Finally, SNARE pairing brings the secretory lysosome membrane in close proximity with the plasma membrane, where the SNARE pairing and Rab molecules can affect a fusion event, thus releasing soluble secretory lysosome content as well as delivering membrane content to the plasma membrane. The mechanisms that regulate granule

Figure 2 A model of secretory lysosome release. (1) A signal is transduced by receptor–ligand interaction, an intracellular signal or by wound formation at the plasma membrane triggering a calcium release from intracellular stores. (2) Synaptotagmin VII (Syn) binds to the secretory lysosome in response to calcium and (3) the vesicle moves toward the MTOC. (4) The secretory lysosome then engages the MT through the motor protein kinesin to move to the periphery of the cell where it is released. (5) For the short movement to the plasma membrane the secretory lysosome engages actin cytoskeletal elements through myosin motors. (6) When the vesicle is in close proximity to the plasma membrane, recognition membrane docking elements (stars) bind the docking elements on the vesicle. (7) The specific vesicular and plasma membrane v and t-SNAREs bind and bring the vesicle near the plasma membrane and fusion occurs (8) releasing soluble and membrane bound secretory lysosome content.

release have not been fully elucidated for each cell type, however, some calcium sensing molecules such as synaptotagmin VII and tethering molecules including synaptobrevin2, Munc13-4 and Munc18-2 along with SNARE molecules Vamp7, Vamp8, Vamp2, Syntaxin4, Syntaxin7, SNAP-23, have been suggested to have a role in cell-specific secretory lysosome release (Logan *et al.*, 2006; Tiwari *et al.*, 2008; Lacy *et al.*, 2001; Suzuki and Verma, 2008). Further, novel SNARE regulatory molecules have recently been identified for platelet granule release (Ye *et al.*, 2014).

Genetic Diseases Associate with Defects in Conventional or Secretory Lysosomes

There are many human diseases associated with defects in conventional lysosome or LRO function or biogenesis and patients have been identified and described for many decades. Some of the diseases associated with conventional lysosome defects include LSDs, which are classified according to the substrates they accumulate. These include mucopolipidosis, sphingolipidoses, oligosaccharidoses, lipoprotein storage disorders, mucopolysaccharidosis, and neuronal ceroid lipofuscinoses along with others, up to 50 have been described (Coutinho *et al.*, 2014; Samie and Xu, 2014). These disorders are most often due to mutations in lysosomally targeted enzymes that degrade their specific substrates or mutations in the proteins that regulate the delivery of these enzymes to the lysosome. The resulting phenotype commonly associated with LSDs is the abnormal accumulation of undegraded substrates. Examples of LSDs that are not due to mutations in the enzymes include mucopolipidosis type 4, where there is a defect in the cation channel mucolipin-1 and Niemann-Pick type C disease, which is due to mutation in either NPC1 or NPC2 (Ikonen and Holtta-Vuori, 2004; Vanier, 2010). It is unclear what ion is important in mucolipid degradation or what ion (s) mucolipin-1 transports (Dong *et al.*, 2008; Dong *et al.*, 2010; Eichelsdoerfer *et al.*, 2010). The exact roles of NPC1 and NPC2 in cholesterol metabolism have not been fully elucidated but they may play a role in sterol transport. Treatment for many of these LSDs is enzyme replacement therapy.

Other genetic diseases associated with the biogenesis, trafficking, or homeostasis of lysosomes and secretory lysosomes that are not due to substrate accumulation include: HPS, GS, CHS, GPS, and FHL. There are nine subtypes of HPS. Phenotypes associated with HPS include pigmentation defects of the hair, skin, and eyes, bleeding tendencies, neurologic disorders, and in some HPS cases pulmonary fibrosis. Mutations in HPS-associated genes encode for proteins that are involved in the biogenesis of secretory lysosomes (e.g., AP3, BLOCs, and geranylgeranyl transferases). As of yet there is no cure for HPS and there is a great deal of heterogeneity of HPS-associated defects (Seward and Gahl, 2013).

There are three types of GS, which can vary in phenotype with partial albinism being the common phenotype, but can include immunodeficiency or neurologic deficits. The genes associated with GS encode for proteins involved in the movement of LROs (e.g., Myosin-Va, Rab27a, and melanophilin). There is no cure for GS but the hematologic problems can be treated with bone marrow transplantation (Arico *et al.*, 2002; Cesaro *et al.*, 2008; Trottestam *et al.*, 2009).

CHS phenotypes include severe immune deficiency, hypopigmentation, bleeding tendency, frequent bacterial infection, oculocutaneous albinism, and progressive neurological dysfunction (Spritz, 1998). The hallmark characteristic of CHS is the presence of giant conventional and secretory lysosomes in all cells of the body (Introne *et al.*, 1999; Shiflett *et al.*, 2002; Stinchcombe *et al.*, 2004). The identification of the gene responsible for CHS was done through classic positional cloning of CHS patients and yeast artificial chromosome complementation using the *beige* mouse model (Perou *et al.*, 1996a; Perou *et al.*, 1996b; Barbosa *et al.*, 1996; Nagle *et al.*, 1996). The *CHS/LYST* gene encodes a protein of 3800 amino acids containing three to four defined domains or motif that have not informed on function (Kaplan *et al.*, 2008) although the WIDL and WD-40 repeat domains defined a family of protein called Beige and Chediak (BEACH) and all family members that have been characterized appear to be involved in membrane trafficking (Cullinane *et al.*, 2013). There are two competing hypotheses for the function of Lyst, one suggesting that Lyst functions as a negative regulator of fusion (Barrat *et al.*, 1999; Kypri *et al.*, 2007; Charette and Cosson, 2007; Rahman *et al.*, 2012; Kypri *et al.*, 2013) and the other suggesting that Lyst regulates lysosome fission (Perou *et al.*, 1997; Durchfort *et al.*, 2012). It is of interest to note that only CHS, as opposed to HPS, GS, or GPS, is associated with defects in conventional lysosomes as well as LROs suggesting that the Lyst protein regulates the maintenance or biogenesis of both types of lysosomes. Treatment for CHS is prophylactic antibiotics early in life and bone marrow transplant, which treats the life-threatening immunologic deficits but does not treat the neurologic defects.

GPS is a rare autosomal recessive bleeding disorder that is due to a reduction or the absence of alpha granules in platelets. The gene identified to be mutated in GPS is *NBEAL2*, which is a member of the BEACH family of proteins involved in vesicular trafficking (Kahr *et al.*, 2011). A mouse model of the disease demonstrated the importance of *Nbeal2* in hemostasis and thrombosis and tissue repair (Deppermann *et al.*, 2013).

FHL patients are immunodeficient but do not exhibit pigmentation defects. FHL is manifested in the first six months of life and is historically treated with bone marrow transplantation (Jabado *et al.*, 1997) or more recently with stem cell transplantation (Ohga *et al.*, 2010). It can be caused by mutations in the *PRF1* gene, which encodes for perforin, the protein that plays an important role in CTL-mediated killing or in the gene encoding Munc13-4 (Feldmann *et al.*, 2003). Munc13-4 protein is essential for the secretion of secretory vesicles from CTL but not from melanocytes or neuronal cells. FHL patient's secretory lysosomes are able to transport and dock to the plasma membrane but are not able to release their content in immunological synapse due to the mutation of Munc13-4. The loss of perforin-mediated cytotoxicity results in imbalanced immune homeostasis and deregulated activation and proliferation of CTLs during antiviral immune response (Lettau *et al.*, 2007).

Conclusions

The biosynthesis of lysosomes and secretory lysosomes involves multiple trafficking pathways including delivery of cargo to the forming lysosome from the endocytic and

biosynthetic pathways along with recycling of membrane constituents needed for further rounds of targeting to the lysosome. There is clear evidence that these organelles are capable of fusion and fission events and the machinery that regulates this process is being elucidated. One of the major limitations in understanding the biogenesis of lysosomes and secretory lysosomes is the ability to distinguish between late endosomes and lysosomes. Currently there are no clear markers of lysosomes, as late endosomes receive 'lysosomal' cargo to be delivered to the forming lysosome. Further, we do not understand many of the molecules that are involved in lysosome or secretory lysosome fission.

Many of the molecular components required for secretory lysosome biogenesis and secretion have been determined, however, it is clear that the detailed biochemical requirements for this process need to be better understood. That particular cell types have evolved mechanisms to generate and release secretory lysosomes further demonstrates the complexity of this process. The recent advances in live cell microscopy, protein tagging, and proteomics should provide some of the tools necessary to identify the roles of these and novel proteins and lipids involved in the biogenesis, maintenance, and secretion of lysosomes.

Lysosome-Related Organelles

Glossary

Geranylgeranylation A kind of lipid modification (prenylation) of proteins. A Rab geranylgeranyl transferase (GGT) complex, which is composed of α and β subunits, mediates the addition of C₂₀ geranylgeranyl group to a Cys residue(s) in the C-terminal region of Rab small GTPases. This modification is required for recruitment of Rab proteins to specific organelle membranes.

Melanogenic enzymes Three structurally related enzymes, tyrosinase (Tyr), tyrosinase-related protein 1 (Tyrp1), and dopachrome tautomerase (Dct, also called Tyrp2), catalyze different steps in the melanin synthesis pathway. Tyr is the rate-limiting enzyme that catalyzes the first two steps of melanin synthesis, and functional defects in Tyr cause the albinism of human oculocutaneous albinism type 1 (OCA1) patients and 'albino' mice.

Membrane trafficking A process by which proteins and lipids are transported from one organelle (donor) to another organelle (acceptor) by means of a transport vesicle.

Rab Rab family small GTPases are conserved intracellular molecular switches that regulate membrane trafficking in all eukaryotes. Rab proteins cycle between a GTP-bound active form and a GDP-bound inactive form, and active Rab proteins promote membrane trafficking by recruiting their specific effector molecules. Two enzymes, guanine nucleotide exchange factor (GEF=activator) and GTPase-activating protein (GAP=inactivator), spatiotemporally regulate Rab cycling.

SNARE complex Soluble N-ethylmaleimide-sensitive-factor attachment protein receptor (SNARE) complexes are general fusion machinery that mediate membrane fusion between transport vesicles and target organelle membranes. One vesicle-SNARE (v-SNARE) protein on the vesicle and two or three target SNARE (t-SNARE) proteins on the target membrane assemble into a parallel four-helix bundle (SNARE zippering) that mediates membrane fusion.

Morphology, Composition, and Function of Lysosome-Related Organelles

Lysosomes are major degradative organelles in eukaryotic cells. Their luminal pH is acidic (~5), and a variety of acid hydrolases in their lumen achieve their degradative function. Lysosomes also contain a unique set of highly glycosylated, lysosome-associated membrane proteins (LAMPs), for example, LAMP-1 and LAMP-2, in their limiting membrane (Saftig and Klumperman, 2009). Lysosome-related organelles (LROs) are a group of cell-type-specific membrane compartments in metazoans that share several of the above features with lysosomes, including an acidic pH and containing certain LAMPs (Dell'Angelica *et al.*, 2000). Despite the features they share with lysosomes, LROs are highly diversified in terms of morphology and composition and are present in only certain types of highly specialized cells (Raposo *et al.*, 2007) (representative cell-type-specific LROs are summarized in the first and second columns of Table 1). In contrast to the heterogeneous morphology of lysosomes, each LRO exhibits highly specialized morphology, for example, the dense granules and α -granules in platelets are spherical shaped, the same as the conventional secretory vesicles in endocrine cells; the melanosomes in melanocytes are rugby-ball-shaped; the Weibel-Palade bodies (WPBs) in endothelial cells are cigar-shaped; and the MHC (major histocompatibility complex) class II compartments in antigen-presenting cells and lamellar bodies in pulmonary alveolar type II cells have a multilamellar structure (Figure 1). The composition of each LRO is also highly specialized (Table 1, third column) to maintain its unique morphology and to perform specialized functions.

Melanosomes contain Pmel17 protein fibrils, on to which melanins are deposited, and WPBs contain von Willebrand factor (vWF) tubules (Figure 1). Because of the differences in structure and composition of LROs, each LRO possess a unique biological function(s) (Table 1, fourth column). The same as lysosomes undergo exocytosis under specialized conditions, for example, during plasma membrane repair, most LROs undergo exocytosis, that is, secretion of the luminal content of the LROs into the extracellular space by fusion between LROs and the plasma membrane, in response to extracellular stimuli, and so these secretory LROs are also called secretory lysosomes (Blott and Griffiths, 2002). The secretory functions of LROs are crucial for many aspects of biological activities in higher animals, including pigmentation (transfer of melanins from melanocytes to keratinocytes), hemostasis (secretion of clotting factors by platelets and endothelial cells), immunity (secretion of perforin and granzymes by cytotoxic T lymphocytes for target cell killing), and lung plasticity (surfactant secretion by alveolar type II cells).

Biogenesis and Transport of LROs

The mechanisms of biogenesis of each LRO are thought to differ considerably to maintain its unique morphology and composition, although several key factors appear to be involved in the biogenesis of all LROs (Marks *et al.*, 2013). However, all LROs are formed in a stepwise manner from immature LROs to mature LROs by acquiring specific cargos via membrane trafficking, a process that transports proteins

Table 1 Cell-specific LROs and their functions

Organelle	Cell type	Major content	Physiological function
Melanosomes	Melanocytes and RPE cells	Melanin and melanogenic enzymes	Melanin synthesis, storage, and pigmentation
Lytic granules ^a	Cytotoxic T lymphocytes and NK cells	Perforin and granzymes	Target cell killing
Dense granules ^a	Platelets and megakaryocytes	ATP, ADP, and serotonin	Blood clotting
α Granules ^a	Platelets and megakaryocytes	Fibrinogen, vWF, and P-selectin	Platelet adhesion and blood clotting
Basophilic granules ^a	Basophils and mast cells	Histamine and serotonin	Inflammation
MHC class II compartments ^a	Dendritic cells, B lymphocytes, and macrophages	MHC class II	Antigen presentation
Azurophilic/primary granules ^a	Neutrophils	Myeloperoxidase and defensins	Antimicrobial defense
Osteoclast granules ^a	Osteoclasts	Lysosomal hydrolyzes	Bone resorption and remodeling
Lamellar bodies ^a	Pulmonary alveolar type II cells	Surfactant phospholipids	Surfactant storage and secretion
Weibel–Palade bodies ^a	Endothelial cells	vWF and P-selection	Blood clotting and inflammation
Notochord vacuoles	Notochord	Not identified ^b	Morphogenesis of the body axis and spine
Pigment granules	<i>Drosophila melanogaster</i> eye cells	Eye pigments	Eye pigmentation
Fat storage organelles	<i>Caenorhabditis elegans</i> gut cells	Lipofuscin	Fat storage

^aBecause these lysosome-related organelles undergo exocytosis in a stimulus-dependent manner, they are also called secretory lysosomes. The stimulus for exocytosis varies with the cell types.

^bNotochord vacuoles were assumed to contain glycosaminoglycans, but recent evidence shows that zebrafish notochord vacuoles do not contain glycosaminoglycans.

Abbreviations: ADP, adenosine diphosphate; ATP, adenosine triphosphate; LROs, lysosome-related organelles; MHC, major histocompatibility complex; NK, natural killer; RPE, retinal pigment epithelial.

Figure 1 Unique morphology of LROs. Schematic representation of dense granule and α -granule (both spherical shaped) in platelets (top row); melanosome in melanocytes (rugby-ball-shaped) and WPB (cigar-shaped) in endothelial cells (middle row); and MHC class II compartment (multilamellar structure) in antigen-presenting cells and lamellar body (multilamellar structure) in pulmonary alveolar type II cells (bottom row).

and lipids from a donor organelle to an acceptor organelle by means of a vesicle carrier and generates a unique luminal environment. LROs may have different origins,

because four representative immature LROs, that is, immature melanosomes, immature WPBs, immature α -granules, and immature lytic granules, all originate from a different organelle sources (Marks *et al.*, 2013). Immature melanosomes are non-pigmented membrane compartments that contain few intraluminal vesicles and cytosolic coats, and they are thought to be derived from early endosomes (see next section for details). Immature WPBs originate from the *trans*-Golgi network (TGN) and assembly of vWF, a major content of WPBs, into tubules enables to form a cigar-shaped immature WPBs. α -Granules originate from the late endosomes or multivesicular endosomes in megakaryocytes. Immature lytic granules are likely to be transformed lysosomes that mature upon T-cell activation, because lytic granules and classical lysosomes are not simultaneously present in cytotoxic T lymphocytes. After the formation of immature LROs, their specific cargo molecules are transported by either the biosynthetic pathway, the endocytic pathway, or both pathways for their maturation. Mature LROs must be transported to the specific intracellular site where they function. Secretory LROs/lysosomes (and melanosomes) must be transported to just beneath the plasma membrane, where they exocytose, along two different cytoskeletons, microtubules and actin filaments. Specific kinesins (microtubule-based anterograde motors), dynein (a microtubule-based retrograde motor), and myosins (actin-based motors) (Akhmanova and Hammer, 2010) are thought to be involved in the transport of LROs, but the exact mechanism of transport of each LRO is not fully understood. Below is a description of the molecular basis of a representative example of the biogenesis and transport machineries of LROs, that is, melanosome biogenesis and transport machineries in epidermal melanocytes.

Molecular Basis of Melanosome Biogenesis and Transport

Melanosomes are the melanin-containing organelles that are responsible for pigmentation of the hair and skin of mammals. Because melanosomes are visible under a light microscope, they are often regarded as a representative model for analyzing LRO biogenesis and transport (Nascimento *et al.*, 2003; Wasmeier *et al.*, 2008). Melanosomes are classified into stages I to IV based on their morphology and degree of maturation (Figure 2, top). Stage I and stage II melanosomes are immature melanosomes (also called premelanosomes), and because of the absence of melanogenic enzymes they are not pigmented. Stage I melanosomes are non-pigmented endosomal compartments that contain few intraluminal vesicles and cytosolic coats and are also called coated endosomes. Their intraluminal vesicles serve as a scaffold for polymerizing melanocyte-specific Pmel17 amyloid fibrils into sheets, which help to form rugby-ball-shaped stage II melanosomes. Stage III melanosomes are less-pigmented melanosomes that contain three melanogenic enzymes, that is, tyrosinase (Tyr), tyrosinase-related protein 1 (Tyrp1), and dopachrome tautomerase (Dct), and other proteins required for melanosome maturation, including a putative transporter oculocutaneous albinism type 2 (OCA2, also called P protein), via post-Golgi trafficking or endosomal trafficking. These trafficking pathways are finely tuned by a set of molecules, including biogenesis of lysosome-related organelles complex-1 ~ 3 (BLOC-1 ~ 3) (Dell'Angelica, 2004), adaptor protein (AP) complex (Bonifacino and Traub, 2003), and Rab small GTPases (Stenmark, 2009). Melanins synthesized by the melanogenic enzymes are deposited on Pmel17 sheets, and mature stage IV melanosomes are formed.

Because melanosomes mature around the nucleus, they need to be transported to the cell periphery along two different cytoskeletons and they are eventually transferred from the dendrites of melanocytes to neighboring keratinocytes and hair matrix cells for pigmentation of mammalian skin and hair, respectively (Figure 2, middle). Mature melanosomes are first transported to the cell periphery along microtubules by a kinesin motor that powers anterograde movement on microtubules, then transferred to actin filaments, and then finally transported to just beneath the plasma membrane along actin filaments by an actin-based motor myosin-Va (Ohbayashi and Fukuda, 2012). Mature melanosomes anchored to the plasma membrane or actin filaments are eventually transferred from melanocyte dendrites to neighboring keratinocytes and hair matrix cells by mechanisms that are largely unknown (Wu and Hammer, 2014). In contrast to mammalian melanosomes, the melanosomes in fish and amphibian melanophores, which are equivalent to the melanocytes in mammals, are rapidly transported bidirectionally in response to extracellular stimuli and are not transferred to neighboring cells. Their bidirectional movements are regulated by coordination of two microtubule-based motors, kinesin and dynein. Rapid changes between two melanosome distribution states, melanosome aggregation around the nucleus and peripheral melanosome dispersion, in melanophores accounts for the changes in the body color of fishes and amphibians that serve to camouflage them.

The best characterized melanosome transport system is the actin-dependent melanosome transport system, which, in

vertebrates, is composed of three conserved molecules, Rab27A, Slac2-a (also called melanophilin), and myosin-Va (Fukuda, 2013). Rab27A is a member of the small GTPase Rab family and specifically localizes to mature melanosomes, when it binds GTP, that is, when Rab27A is activated. The active Rab27A on the melanosome then recruits its specific effector molecule Slac2-a via the N-terminal Slp homology domain (SHD=Rab27A effector domain). Slac2-a also contains a myosin-Va-binding domain in the middle of the molecule and functions as a linker protein between Rab27A on the melanosome and myosin-Va (Figure 2, bottom). The resulting tripartite protein complex composed of Rab27A, Slac2-a, and myosin-Va facilitates melanosome transfer from microtubules to actin filaments and regulates actin-dependent melanosome transport.

Although the above-described actin-dependent melanosome transport machinery is highly conserved both in mammalian melanocytes and in lower vertebrate melanophores, the microtubule-dependent melanosome transport systems of melanocytes and melanophores appear to differ, because heterotrimeric kinesin-2/Kif3 regulates microtubule-dependent anterograde melanosome transport in melanophores, whereas kinesin-1/Kif5 seems to be involved in microtubule-dependent anterograde melanosome transport in melanocytes. The precise mechanism of microtubule-dependent anterograde melanosome transport in melanocytes remains elusive, but it has been suggested that a specific Rab isoform may be involved in the process, possibly as a cargo receptor for the kinesin motor (Ishida *et al.*, 2012), in the same way that Rab27A functions as a cargo receptor for actin-dependent melanosome transport.

Genetic Diseases Associated with Defects in LRO Biogenesis and Transport

Because LROs play important roles in various biological activities, defects in LRO biogenesis or transport are known to cause human diseases, including albinism, immunodeficiency, and pulmonary fibrosis. Defects in melanosome biogenesis or transport cause pigmentary disorders in hair, skin, and/or eyes, for example, a functional defect in Tyr, a key enzyme in the melanin synthesis pathway in melanocytes, cause human oculocutaneous albinism type 1 (OCA1) (Tomita and Suzuki, 2004). Abnormalities in the biogenesis or transport of LROs in immune cells are associated with immunological disorders, for example, mutations of perforin, a major cargo of lytic granules in cytotoxic T lymphocytes that is responsible for their killing activity, cause familial hemophagocytic lymphohistiocytosis type 1 (FHL1). Lamellar body dysfunction in pulmonary alveolar type II cells is associated with pulmonary fibrosis. It is particularly noteworthy that the functions of several of the same LROs are impaired in patients with certain human genetic diseases, including Griscelli syndrome (GS), Hermansky-Pudlak syndrome (HPS), and Chédiak-Higashi syndrome (CHS). Patients with these syndromes have certain symptoms in common, including silvery hair (a symptom of melanosome dysfunction), pale blue eyes (a symptom of melanosome dysfunction), and bleeding tendency (a symptom of platelet granule dysfunction), thereby indicating that

Figure 2 Biogenesis and transport of melanosomes in mammalian epidermal melanocytes. (Top) Schematic representation of the stepwise development of a mature melanosome. The stage I immature melanosome with intraluminal vesicles is derived from early endosomes. The stage II immature melanosome contains Pmel17 fibrils. Melanogenic enzymes, for example, tyrosinase (Tyr) and tyrosinase-related protein 1 (Typr1), are transported to the stage III melanosome, where melanin synthesis takes place. The stage IV melanosome is a mature melanosome. (Middle) Melanosomes form and mature around the nucleus. Mature melanosomes are transported to just beneath the plasma membrane along two different cytoskeletons, microtubules and actin filaments. Melanosomes are eventually transferred from the dendrites of melanocytes to neighboring keratinocytes. (Bottom) Mature melanosomes are transported to the cell periphery by motor protein complexes along different cytoskeletons, that is, microtubules and actin filaments. An actin-based melanosome transport complex composed of Rab27A, Slac2-a/melanophilin, and myosin Va, deficiency of each of which causes the hypopigmentation of GS2/ashen, GS3/leaden, and GS1/dilute, respectively.

Table 2 Genetic diseases associated with defects in a subset of LROs

Protein name	Human disease	Mouse model	Proposed function
Griscelli syndrome (GS)			
Myosin-Va	GS1	dilute	An actin-based melanosome transport complex composed of Rab27A, Slac2-a, and myosin-Va
Rab27A	GS2	ashen	
Slac2-a/melanophilin	GS3	leaden	
Chédiak–Higashi syndrome (CHS)			
CHS1/LYST	CHS	beige	Lysosome fission
Hermansky–Pudlak syndrome (HPS) ^a			
AP-3 β 3A	HPS2	pearl	A heterotetrameric adaptor complex (AP) that mediates cargo sorting from endosomes to LROs
AP-3 δ		mocha	
Pallidin	HPS9	pallid	Together with snapin, BLOS1, and BLOS2, these proteins form a BLOC-1 complex that contributes to t-SNARE regulation
Cappuccino		cappuccino	
Muted		muted	
Dysbindin	HPS7	sandy	
BLOS3a	HPS8	reduced pigmentation	
HPS3	HPS3	cocoa	A BLOC-2 complex composed of three subunits that functions downstream of BLOC-1 in cargo transport
HPS5	HPS5	ruby eye-2	
HPS6	HPS6	ruby eye	
HPS1	HPS1	pale ear	A heterodimeric guanine nucleotide exchange factor (HPS1–HPS4) for Rab32/38
HPS4	HPS4	light ear	
Rab38		chocolate	
Vps33a		buff	A subunit of the Vps-C complex
Rabggta		gunmetal	The α subunit of Rab GGT II complex, which mediates prenylation of Rab proteins

^aThe normal proteins related to HPS are classified into six groups based on their function: AP-3 complex, BLOC-1 ~3 complexes, Vps-C complex, and Rab GGT II complex (see [Figure 4](#)).

Abbreviations: GGT, geranylgeranyl transferase; LROs, lysosome-related organelles.

Source: Adapted from Raposo, G., Marks, M.S., Cutler D.F., 2007. Lysosome-related organelles: Driving post-Golgi compartments into specialization. *Current Opinion in Cell Biology* 19, 394–401; Wei, A.H., Li, W., 2013. the same factors are involved in the biogenesis or transport of several LROs, despite the fact that the morphology and function of the LROs involved differ considerably. The mouse models (coat color mutant mice) of three well-known human syndromes whose manifestations are attributable to impaired biogenesis or function of several LROs, that is, of GS, HPS, and CHS, and the proposed functions of the gene products responsible for the clinical manifestations of these syndromes are described below ([Table 2](#)).

GS

GS is an extremely rare autosomal recessive disorder characterized by silvery hair (partial albinism) at birth. GS is classified into three types, that is, GS1 (mouse model: ‘dilute’), GS2 (mouse model: ‘ashen’), and GS3 (mouse model: ‘leaden’), based on difference between the genes responsible ([Table 2](#)) and in their symptoms ([Van Gele et al., 2009](#)). GS1 is caused by mutations in the *MYOSIN-VA* gene, which encodes an actin-based motor and is characterized by neurological

Figure 3 Normal melanocytes (left, mouse melan-a cells; [Bennett et al., 1987](#)), which have a peripheral melanosome distribution, and Rab27A-deficient melanocytes (right, mouse melan-ash cells), which are characterized by perinuclear melanosome aggregation (i.e., a typical Griscelli syndrome phenotype). Scale bar, 20 μ m. Images were taken by Morié Ishida. Melanosome movements in normal cells and in Slac2-a-deficient cells (equivalent to Rab27A-deficient cells) are shown in the form of Multimedia Annexes ([Video 1](#) and [Video 2](#), respectively).

disorders in addition to partial albinism. GS2 is caused by mutations in the *RAB27A* gene that encodes Rab-type small GTPase (Stenmark, 2009) and is characterized by immunodeficiency in addition to partial albinism. By contrast, GS3 is caused by mutations in the *SLAC2-A/MLPH* gene, which encodes an effector molecule of Rab27A, and it is characterized by partial albinism alone. Melanocytes from GS1~3 patients or their mouse models contain mature melanosomes and are characterized by melanosome aggregation in the perinuclear region, in contrast to the peripheral melanosome distribution of normal melanocytes (Figure 3). Thus, the hypopigmentation of the hair and skin of GS patients is attributable to a defect in melanosome transport, specifically in actin-dependent melanosome transport (Figure 2), and not to a defect in melanosome biogenesis. The gene products responsible for GS1, GS2, and GS3, that is, myosin-Va, Rab27A, and Slac2-a/melanophilin, respectively, cooperatively function in actin-

dependent melanosome transport by forming a tripartite protein complex on mature melanosomes. Rab27A localizes mature melanosomes by C-terminal geranylgeranylation, a lipid modification that anchors Rab27A to the organelle membrane. Slac2-a then directly interacts with Rab27A on the melanosome through its N-terminal SHD and recruits an actin-based motor myosin-Va to the melanosome (Figure 2, bottom). Interestingly, the tripartite protein complex appears to function in certain types of specialized cells, including epidermal melanocytes. For example, Rab27A is indispensable to exocytosis of cytotoxic granules, specifically to the docking step of cytotoxic granules to the plasma membrane, but neither myosin-Va nor Slac2-a is involved in this process, which is consistent with the fact that neither GS1 patients nor GS3 patients exhibit immunodeficiency (Van Gele *et al.*, 2009). Rab27A is thought to regulate the transport of LROs in different cell types through interaction with cell-type-specific or tissue-specific

Figure 4 Schematic representation of six large cytoplasmic protein complexes associated with HPS: AP-3, VPS-C, BLOC-1, BLOC-2, BLOC-3, and Rab GGT II complex (see also Table 2). The VPS-C complex interacts with VPS18, VPS41, and VPS39, to form heterohexamers, named a HOPS complex, which mediates tethering between late endosomes and lysosomes (Solinger and Spang, 2013). Protein interactions between subunits of the BLOC-1 complex are complicated and their interaction networks are not depicted in detail here (see Wei and Li, 2013 for details).

Rab27A effector molecules (Fukuda, 2013): the Rab27A–Slac2-a–myosin-Va complex promotes actin-dependent melanosome transport in epidermal melanocytes, and the Rab27A–Slac2-c/MyRIP–myosin VIIa complex promotes actin-dependent melanosome transport in retinal pigment epithelial (RPE) cells.

HPS

HPS (HPS1 ~ 9) and its corresponding mouse models is a group of genetic disorders that are characterized by silvery hair and bleeding tendency at birth (Table 2) (Wei and Li, 2013). Several types of HPS are also characterized by pulmonary fibrosis due to lamellar body dysfunction in pulmonary alveolar type II cells. Unlike GS, the manifestations of HPS are caused by defects in the biogenesis of LROs, not in their transport, for example, malformation of melanosomes, specifically the transport of melanogenic enzymes to melanosomes, is the primary cause of the hair and skin hypopigmentation in HPS patients. The gene products responsible for HPS are subunits of large cytoplasmic protein complexes and have been classified into six different groups: adaptor protein complex (AP)-3, vacuolar protein sorting (VPS)-C, biogenesis of lysosome-related organelles complex (BLOC)-1, BLOC-2, and BLOC-3, and Rab geranylgeranyl transferase (GGT) II complex (Table 2 and Figure 4). All of these protein complexes are thought to be involved in sorting or transporting membrane cargo proteins to LROs, for example, melanogenic enzyme tyrosinase to melanosomes. AP-3 is a heterotetrameric adaptor that recognizes cytoplasmic signals of transmembrane cargo proteins and packs them into transport vesicles (Dell'Angelica, 2009). VPS-C is a heterotetrameric complex (VPS11, 16, 18, and 33) that is thought to regulate tethering and SNARE (soluble N-ethylmaleimide-sensitive-factor attachment protein receptor)-dependent fusion of transport vesicles to LROs (Solinger and Spang, 2013). BLOC-1, BLOC-2, and BLOC-3 are composed of eight subunits, three subunits, and two subunits, respectively, and are involved in the transport of transmembrane cargo proteins to LROs, although the exact functions of BLOC-1 and BLOC-2 remain largely unknown (Dell'Angelica, 2004). BLOC-3 functions as a heterodimer guanine nucleotide exchange factor (activator) for small GTPases Rab32 and Rab38, and a mutation in the mouse *rab38* gene causes the hypopigmentation phenotype of 'chocolate' mice (Marks *et al.*, 2013). Similarly, a functional defect in the Rab GGT II complex that mediates prenylation of Rab proteins results in the HPS-like phenotype of 'gunmetal' mice.

Rab32 and Rab38 redundantly function in the transport of melanogenic enzymes to melanosomes through interaction with their specific effector molecule Varp (VPS9-ankyrin-repeat protein), a scaffold protein that interacts with a variety of proteins, including a vesicle-SNARE VAMP7 (vesicle-associated membrane protein 7)/TI-VAMP (Ohbayashi and Fukuda, 2012). Varp maintains an inactive conformation of VAMP7 during the transport of transmembrane cargo proteins, for example, tyrosinase, after which VAMP7 forms a SNARE complex with two target-SNAREs, syntaxin-3 and SNAP23 (synapto-some-associated protein of 23 kDa), which promotes the transfer of melanogenic enzymes to melanosomes presumably

by mediating membrane fusion between the transport vesicle and the immature melanosome (Yatsu *et al.*, 2013).

CHS

CHS is a rare autosomal recessive disorder that is characterized by silvery hair at birth, and infections and neuropathy are frequently observed in CHS patients. Mutations in the *CHS1*/*LYST* gene are known to cause CHS, but the exact function of the large protein that contains a BEACH domain, whose function is unknown. *LYST* is likely to be involved in the biogenesis of lysosomes and LROs, because these organelles are enlarged in the cells of CHS patients. Thus, *LYST* may promote fission of lysosomes and LROs.

At the Center of Autophagy: Autophagosomes

Glossary

ATG proteins The AuTophagy-related (ATG) proteins are the key players regulating and mediating macroautophagy. On a note, there are also genes essential for the progression of autophagy that are not called ATG.

Autophagosomes They are vesicles with a double lipid bilayer, which are formed during macroautophagy. Autophagosomes sequester and deliver cytoplasmic material into the lysosomes for degradation.

Autophagy An evolutionary conserved lysosomal degradative pathway. The term encompasses 3 processes: macroautophagy, microautophagy, and chaperone-mediated autophagy. Basal autophagy constantly recycles the cytoplasmic components and thereby maintains the cellular homeostasis. When cells are exposed to stress, the enhancement of autophagy contributes to overcome them.

Autophagy receptors Autophagic receptors are a set of proteins that simultaneously bind specifically a structure targeted by autophagy and ATG proteins found in the

interior of autophagosomes, mainly LC3. This property provide the substrate specificity to the selective types of autophagy.

PAS The Phagophore Assembly Site or Pre-Autophagosomal Structure is the nucleation site where the ATG proteins assemble to first generate a phagophore and subsequently expand it into an autophagosome. In yeast there is one PAS per cell whereas in mammalian cells there are several per cell.

Phagophore (also known as isolation membrane) The phagophore is a membrane cistern that is the precursor structure of the autophagosome. It is formed at the PAS by the orchestrated actions of the ATG proteins, which also elongate it into an autophagosome.

Selective autophagy This term describes forms of macroautophagy in which a specific structure (i.e. an aggregate, organelle, or microbe) is specifically and exclusively sequestered by autophagosomes.

Macroautophagy and Autophagosomes

Macroautophagy can be distinct from the two other forms of autophagy, namely, chaperon-mediated autophagy and microautophagy, because it involved the formation of autophagosomes (Mizushima *et al.*, 2008; Kraft and Martens, 2012). Macroautophagy (hereafter autophagy) is an evolutionary conserved cellular pathway that is active at basal levels in every cell. Thus, cytoplasmic material including unfolded or obsolete proteins, and damaged organelles are continuously degraded into lysosomes even if the flux of autophagy can vary from tissue to tissue. The constant turnover of the cytoplasmic components by autophagy is crucial in maintaining cellular homeostasis and also provides metabolites such as amino acids, sugars, nucleotides, and lipids to generate new macromolecules (Kraft and Martens, 2012; Levine and Kroemer, 2008; Figure 1). Autophagy can be further stimulated when a cell is exposed to cellular stresses such as nutrient starvation and helps the cell to overcome them (Shintani and Klionsky, 2004). The physiological relevance of this type of responses was initially revealed by a study showing that mice unable to undergo autophagy are unable to survive the postnatal starvation period and die shortly after birth (Kuma *et al.*, 2004). In addition to stresses, specific developmental programs, immune responses and numerous other signals can also induce autophagy (Levine *et al.*, 2011; Choi *et al.*, 2013; Mizushima and Levine, 2010).

Together with the proteasome, autophagy is one of the two major protein degradation pathways of the cell. However, while the proteasome is mainly devoted to the turnover of short-lived proteins, autophagy degrades long-lived

proteins but also numerous other cell components including sugar chains, nucleotides and lipids. While in specific situations autophagosomes randomly sequester cytoplasmic material, often their cargo is a specific structure (Wong and Cuervo, 2010). Selective types of autophagy include the turnover of organelles (e.g., mitochondria, peroxisomes, ER, lysosomes, lipid droplets...), protein aggregates, large complexes (ribosomes, mid-bodies, inflammasome...) and invading pathogens (Choi *et al.*, 2013). These forms of autophagy rely on a series of the so-called autophagy receptors, which recognize the targeted structure and mediate the subsequent recruitment and assembly of the ATG machinery (Boyle and Randow, 2013; Isakson *et al.*, 2013). This results in the formation of the autophagosome around the selected material providing the specificity to this process (Shintani and Klionsky, 2004; Figure 2). Because of this ability to specifically eliminate unwanted structures, autophagy plays a crucial function in a multitude of physiological processes in eukaryotic organisms. This pathway is thus part of our innate immune response through its ability to target invading pathogens for degradation (Levine *et al.*, 2011). Moreover, the turnover of protein aggregates prevents an early onset of neurodegenerative disorders like Huntington's or Alzheimer's disease (Choi *et al.*, 2013). Autophagy also plays major roles in development and cell differentiation in multicellular organisms and contributes to their longevity (Yoshimori, 2007; Melendez *et al.*, 2003). As a result, an impairment or defect in autophagy causes a variety of human illnesses, including neurodegenerations, cancer, inflammatory diseases, and muscular dystrophies (Levine and Kroemer, 2008; Choi *et al.*, 2013).

Figure 1 The mechanism of autophagy. Autophagy starts with the formation of a membrane cistern called the phagophore, where all the ATG proteins localize to. Often the initial phagophore is formed in close proximity to the ER. In addition to this organelle, other cellular compartments such as mitochondria, the plasma membrane, the Golgi complex and recycling endosomes have been postulated to contribute membranes to form the phagophore and then expand it into an autophagosome. During the formation of autophagosomes, the cytoplasmic material is sequestered within the forming vesicle. Complete autophagosomes fuse either directly with lysosomes to form autolysosomes or with endosomes to generate an organelle called amphisome. This latter eventually fuse with lysosomes too. In the lysosome lumen, resident hydrolases degrade the autophagosomal cargo and the resulting metabolites are transported back in to the cytoplasm by lysosomal permeases. The autophagosome can also fuse with the plasma membrane and thereby being one of the mechanisms for unconventional secretion.

Figure 2 The different types of selective autophagy. In addition to the unspecific sequestration of cytoplasmic material (i.e., bulk degradation), autophagosomes can also specifically target a variety of cellular components. Depending on the conditions, autophagosomes can selectively and exclusively engulf mitochondria (i.e., mitophagy), ribosomes (i.e., ribophagy), peroxisomes (i.e., pexophagy), lysosomes (i.e., lysophagy), parts of the ER (i.e., ERphagy), protein aggregates (i.e., aggrephagy), pathogens (i.e., xenophagy), or lipid droplets (i.e., lipophagy; not shown here), and transport these cell components to the lysosomes for degradation.

General Characteristics of Autophagosomes

Autophagosomes were first described by the Nobel laureate Christian de Duve in 1966 (De Duve and Wattiaux, 1966). One of the peculiarities of these carriers in comparison to other

transport vesicles is their double lipid bilayer, which has also a low content in transmembrane proteins. Therefore, autophagosomes appear as very smooth vesicles when analyzed by freeze-fracture electron microscopy (Fengsrud *et al.*, 2000). Their size can vary from 500 nm up to 1.5 μ m and this flexibility allow them to sequester cargoes of different sizes (Fengsrud *et al.*, 2000; Klionsky *et al.*, 2012; Mizushima *et al.*, 2002). In contrast to other transport vesicles, an autophagosome is formed *de novo*, that is, not through budding from a pre-existing organelle, and it sequesters cytoplasmic cargo material during its completion. This different solution adopted by the cell to generate a vesicle is probably due to the topology of the cargo, which is cytoplasmic, and therefore cannot be engulfed by a single lipid bilayer with exposed extremities, something thermodynamically highly unfavorable (Reggiori and Klionsky, 2013).

The autophagic vesicles are categorized based on their morphology into early autophagosomes and late autophagosomes or autolysosomes. In early autophagosomes the sequestered cargo is morphological unchanged and whole organelles or part of organelles are found in the autophagosomal lumen. Late autophagosomes or autolysosomes are fused with lysosomes and the sequestered cargo is already being degraded (Yla-Anttila *et al.*, 2009b).

Generation of the Autophagosomes: The Machinery

The initial characterization of the molecular machinery mediating the biogenesis of autophagosomes has mostly been done in the yeast *Saccharomyces cerevisiae*. In particular the genes mediating the process of autophagy were identified through genetic screens in this organism and they are currently

called the AuTophagy-related (ATG) genes. This discovery was the breakthrough in the autophagy research because the high degree of conservation of numerous ATG genes allowed identifying their counterparts in high eukaryotes. To date 36 ATG genes have been characterized in yeast and many of them have human orthologs (Klionsky *et al.*, 2003; Yang and Klionsky, 2010). In high eukaryotes there are additional genes essential for autophagy that are not called ATG. It is now established that the generation of autophagosomes is regulated by a hierarchical interplay of the ATG proteins and it is divided in 3 discrete steps: (1) initiation, (2) nucleation, and (3) elongation and closure.

Initiation of autophagy is mediated by the ULK/ATG1 complex. The mammalian ULK kinase complex is composed of ULK1/2 (unc-51-like kinase), FIP200 (focal adhesion kinase family interacting protein of 200 kD), ATG13, and ATG101. The ULK/ATG1 complex is differentially regulated by TORC1 (mammalian target of rapamycin complex 1) and AMPK (AMP-activated protein kinase), and possibly by other signaling cascades. In particular, active TORC1 inhibits the ULK/ATG1 complex whereas active AMPK stimulates the ULK/ATG1 complex (He and Klionsky, 2009; Yang and Klionsky, 2010). TORC1, with its central serine/threonine kinase mTOR (mammalian target of rapamycin), acts as a nutrient sensor in the cell and is activated in presence of nutrients. Under these conditions, through phosphorylation, TORC1 inhibits both AMPK and the ULK/ATG1 complex, to which it is bound. In nutrient-deprived cells, in contrast, AMPK is activated and phosphorylates TORC1 leading to its inhibition and dissociation from the ULK/ATG1 complex. In addition, AMPK phosphorylates the ULK/ATG1 complex and thereby activates it. The activation by AMPK and simultaneously release of inhibition by the TORC1 stimulates the ULK/ATG1 complex kinase activity initiating the autophagic process (He and Klionsky, 2009; Yang and Klionsky, 2010).

After the initiation step, the ATG proteins assemble at cellular structures that has been called the phagophore assembly site or pre-autophagosomal structure (PAS). In mammalian cells numerous early autophagosomal structures can be observed upon autophagy induction whereas only one PAS is generated in yeast. The assembly of the ATG proteins, called nucleation, requires the local generation of the phosphoinositol-3-phosphate (PtdIns3P). PtdIns3P is generated by the PtdIns3 kinase class 3 (PtdIns3KC3), also called hVPS34. This protein is in complex with the regulatory factors BECLIN1/ATG6 and p150 (human VPS15), which together compose the PtdIns3KC3 complex (Simonsen and Tooze, 2009). The insertion of BECLIN1 into the PtdIns3KC3 complex is negatively regulated by BCL-2 protein family members and positively stimulated by the ULK complex (Russell *et al.*, 2013; Pattinger *et al.*, 2005). The PtdIns3KC3 complex fulfils several functions in autophagy and in endosomal vesicle transport pathways depending on which proteins are associated with the complex. Binding of ATG14L (or Barkor) and AMBRA1 (activating molecule in BECLIN1-regulated autophagy) to the PtdIns3KC3 complex recruits the complex to the PAS stimulating autophagosome formation (Kang *et al.*, 2011). When this complex is associated with UVRAG (ultraviolet irradiation resistant-associated gene), which is in turn bind to BIF-1 (Bax-interacting factor 1), it is engaged in autophagosome maturation as well

as endocytotic trafficking (Kang *et al.*, 2011). However, when UVRAG is interacting with RUBICON (RUN domain and cysteine-rich domain containing, BECLIN1-interacting protein), autophagosome maturation is blocked (He and Klionsky, 2009; Kang *et al.*, 2011).

While the precise role of PtdIns3P in autophagy is unclear, it is known that the phagophore is formed at PtdIns3P rich regions mostly adjacent to the ER. It is also clear that this lipid mediates the recruitment of PtdIns3P-binding proteins (also called PtdIns3P effector proteins) that are necessary for autophagosome biogenesis to the PAS (Mari *et al.*, 2011; Isakson *et al.*, 2013; Codogno *et al.*, 2012). Several of these PtdIns3P effector proteins are known that are involved in autophagosomal formation, including ALFY, DFCP1, and WIPI protein family members (homologs to the yeast ATG18). It was shown in yeast that ATG18 localization to the PAS depends on its interaction with ATG2 and the presence of PtdIns3P (Obara *et al.*, 2008; Rieter *et al.*, 2013). The ATG18-ATG2 complex interacts with ATG9, the only transmembrane ATG protein, at the PAS (Reggiori *et al.*, 2004). ATG9 thereby at least partially contributes membranes to the forming phagophore even if its interaction with the forming autophagosomes is very dynamic in both yeast and mammalian cells (Mari *et al.*, 2011; Isakson *et al.*, 2013; Codogno *et al.*, 2012; Chan and Tang, 2013; Orsi *et al.*, 2012; Yamamoto *et al.*, 2012).

The elongation and closure of the phagophore (also called isolation membrane), the third step in autophagosome biogenesis, is mainly executed by two ubiquitin-like conjugation systems, which have the ultimate result of forming the ATG16L1 complex and of lipidating the members of the ATG8/LC3 (microtubule associated protein 1 light chain 3) protein family (Shpilka *et al.*, 2012; Yang and Klionsky, 2010). The formation of the ATG16L1 complex as well as the LC3 lipidation are essential for the autophagosome biogenesis. The ATG16L1 complex contains the ATG12-ATG5 conjugate. The formation of this complex is mediated by the E1-like enzyme ATG7, which activates ATG12 and transfers it to ATG10, an E2-like enzyme, which finally covalently binds ATG12 to ATG5. The ATG12-ATG5 conjugate interact with ATG16L1 to form a multimeric complex, the ATG16L1 complex, which localizes to the phagophore and early autophagosome intermediates but dissociates from complete autophagosomes (Ohsumi and Mizushima, 2004; Yang and Klionsky, 2010).

In the second conjugation system, LC3 becomes linked to phosphatidylethanolamine (PE). Initially a preform of LC3 is posttranslationally cleaved at the C-terminus by the ATG4 proteases. The resulting cytoplasmic form of LC3, also called LC3-I, gets also activated by the E1-like enzyme ATG7 and transferred onto ATG3, another E2-like enzyme before being conjugated to PE. The ATG16L1 complex promotes this latter step by specifically bringing ATG8-ATG3 in proximity of the PE pool present in the autophagosomal membranes. The LC3-PE conjugate, also known as LC3-II, is present in the inner as well as at the outer surface of the expanding autophagosomal membrane. Prior to the autophagosome fusion with lysosomes, the LC3-II pool on the outer autophagosomal membrane is released from PE by ATG4 for reuse (Kabeya *et al.*, 2000; Yang and Klionsky, 2010; He and Klionsky, 2009). The fact that a subpopulation of LC3 is present in the interior

of autophagosomes makes this protein the ideal marker to monitor the generation of these carriers and their subsequent fusion with lysosomes (Kabeya *et al.*, 2000). In particular LC3 subcellular distribution can be analyzed by fluorescence microscopy and the redistribution of this protein from the cytoplasm into punctuate structures, for example, the autophagosomes, is an indicator of autophagy induction. Furthermore it allows assessing autophagy induction and progression by analyzing the LC3-II protein levels by Western blot (Klionsky *et al.*, 2012; Mizushima, 2004; Rubinsztajn *et al.*, 2009).

Generation of the Autophagosomes: The Membranes

While enormous progresses have been done regarding the characterization of the ATG machinery, the origin of the autophagosomal membranes is still not clear. Membranes from multiple sources have been shown to contribute to the formation and maturation of autophagosomes; therefore, this topic is the subject of intense debate and research. Amongst these there are several organelles, including the plasma membrane (Ravikumar *et al.*, 2010), early endosomes (Razi *et al.*, 2009), the mitochondria (Hailey *et al.*, 2010), recycling endosomes (Longatti and Tooze, 2012; Puri *et al.*, 2013), the Golgi complex (Mari *et al.*, 2011; Orsi *et al.*, 2010) and the ER (Axe *et al.*, 2008; Hayashi-Nishino *et al.*, 2009; Yla-Anttila *et al.*, 2009a; Figure 1). In fact, it was shown that most of the autophagosomes form in close association with the ER, in a structure called the omegasome (Axe *et al.*, 2008; Hayashi-Nishino *et al.*, 2009; Yla-Anttila *et al.*, 2009a). The omegasome is a PtdIns3P rich subdomain of the ER that is formed upon starvation. It is a dynamic structure where ATG proteins required for the nucleation step assemble and which gives rise to phagophores and then autophagosomes (Axe *et al.*, 2008; Hayashi-Nishino *et al.*, 2009; Yla-Anttila *et al.*, 2009a). The autophagosomes, however, do not bud or form directly from the ER but rather originate in close proximity of this organelle, possibly in regions that most likely are in close contact with mitochondrial membranes, that is, the so-called mitochondria-associated membranes (Hamasaki *et al.*, 2013).

Maturation and Consumption of Autophagosomes

Once complete, autophagosomes fuse either directly with lysosomes or with endosomes to form an intermediate organelle called amphisome. Amphisomes ultimately fuse with lysosomes too. These events lead to progressive maturation of autophagosomes into a degradative compartment, the autolysosome, through the acquisition of low pH and lysosomal hydrolases, which access the autophagosomal cargo and mediate its turnover (He and Klionsky, 2009; Figure 1). The precise mechanism of how the autophagosome fuses with the lysosomes has not yet been fully resolved. However, members of both the Rab GTPase and the SNARE (soluble N-ethylmaleimide-sensitive-factor attachment protein receptor) protein families as well as a low intralysosomal pH have been shown to be involved in fusion (Bento *et al.*, 2013; Moreau *et al.*, 2013; Yamamoto *et al.*, 1998). During the autophagosome fusion events, only the outer lipid bilayer of

these double-membrane carriers fuses with the lysosomal limiting membrane and as a result the inner autophagosomal vesicle is also degraded within the autolysosome. The resulting material is finally transported by lysosomal membrane permeases out of the autolysosome lumens into the cytoplasm, where it can be metabolized by the cell (He and Klionsky, 2009; Figure 1).

For more efficient fusion between them, autophagosomes and lysosomes have to come into close proximity. This is accomplished on the one hand through the active transport of the autophagosomes via microtubules from the cell periphery to the microtubule organization center (MTOC) (Bento *et al.*, 2013). On the other hand, lysosomal positioning within the cell is regulated in a nutrient-dependent manner by mTOR. That is, under growing conditions lysosomes bind to a kinesin complex that mediated their positioning at the cell periphery. Under starvation, an increase in the intracellular pH provokes an inhibition of the recruitment of the kinesin complex to the lysosomal membrane and thereby allowing lysosomes to move to the MTOC (Bento *et al.*, 2013).

Autophagosomes not only fuse with compartments of the endo-lysosomal system. Recent findings support the notion that these carriers could also fuse with the plasma membrane (Deretic *et al.*, 2012). This nondegradative function of autophagy plays a role in the unconventional secretion (i.e., secretion that does not involve transport through Golgi apparatus) of a subset of signal molecules (Deretic *et al.*, 2012). Diverting of autophagosomes from their conventional trajectory to the endo-lysosomal system is also something implemented by certain pathogens, mainly bacteria, to supply their intracellular inclusions with nutrients and thus fuel their replication and differentiation (Amer, 2013).

Peroxisomes

PB Lazarow, Institut Pasteur, Paris, France

© 2016 Elsevier Inc. All rights reserved.

Introduction and Morphology

The peroxisome is a beautiful organelle to behold, whether glowing in the fluorescence microscope as a sea of green dots (Figure 1(A)), or showing off its finely granular matrix, sometimes with a paracrystalline core, in the electron microscope (Figure 1(B,C)), or visibly green to the human eye when purified from rat liver (green due to the high concentration of catalase). Most peroxisomes are spherical or ovoid, bounded by one membrane bilayer, and approximately 100–200 nm in diameter. In some cells they are 5 or 10 times bigger, for example, in hepatocytes, and sometimes they are tubular in form. A peroxisome reticulum of interconnected organelles was suggested from serial section analyses of peroxisomes with tails and tubular elements (Lazarow *et al.*, 1980) and has been seen in living COS-7 cells by real-time imaging (Schrader *et al.*, 2000) and in regenerating rat liver (Yamamoto and Fahimi, 1987). In exceptional cases, (e.g., the sebaceous preputial gland) the peroxisomes form large cup-shaped elements interconnected into elaborate branching structures (Gorgas, 1984; Figure 1(E)).

Behind its usually simple appearance, the peroxisome conceals a remarkable diversity of physiological roles and biochemical functions. These vary from plants to fungi to animals, from one tissue to another, and even from one cell type to another within a tissue. The organelle adapts its biochemical composition and its abundance to the needs of the cell and to changing environmental conditions. Nevertheless, there are some functional characteristics common to all peroxisomes (Wanders and Waterham, 2006a; Palma *et al.*, 2009; Islinger *et al.*, 2010; Hu *et al.*, 2012).

We describe its major physiological roles and discuss how it evolved its diverse biochemical abilities. We look at how peroxisomes multiply and adapt, how they are formed, remodeled, and degraded, and at the mechanisms that control this. We end with the human diseases that occur when the peroxisome has a defective enzyme or is not assembled correctly. For reasons of space, most references in this article are necessarily to reviews.

Some Important, Specialized Physiological Functions of Peroxisomes

In the Nervous System: Myelin Formation and Maintenance

Peroxisomes are required for the normal formation of myelin. The predominant phospholipids of myelin are plasmalogens, which contain an unsaturated long-chain alcohol in the place of one of the two fatty acids of the usual phospholipids (Figure 2(a)). Plasmalogens are thought to defend against reactive oxygen toxicity (thanks to their vinyl ether linkage) and to alter membrane flexibility and permeability. Plasmalogen synthesis begins obligatorily in peroxisomes (Braverman

and Moser, 2012; Figure 2(b)). Human patients without this function suffer defective or delayed myelination. Maintaining axonal integrity and myelin sheaths requires the function of oligodendrocyte peroxisomes (Baes and Aubourg, 2009). Plasmalogens are present in many other tissues as well.

Conversion of Fat to Sugar, Supplying Energy to Germinating Plant Seedlings

Many seeds contain a store of fat (in the form of triacylglycerols in lipid droplets) that serves the energy requirements of growing seedlings until they acquire photosynthetic capacity. To do so, fatty acids are cleaved from the triacylglycerols and undergo β -oxidation to form acetyl-CoA, which is then largely converted to glucose via the glyoxylate cycle. In plants, this β -oxidation occurs exclusively in peroxisomes, not in mitochondria. The acetyl-CoA end product formed within peroxisomes is used right where it is produced by glyoxylate cycle enzymes (see details and illustrations below) to form succinate, which is converted to fumarate by mitochondria and then to glucose in the cytosol. If one of the peroxisomal enzymes of β -oxidation or the glyoxylate cycle is defective, plant growth is greatly impaired (Hu *et al.*, 2012; Kunze *et al.*, 2006). Seedling peroxisomes also have been called 'glyoxysomes.'

Sperm Formation

Spermiogenesis depends upon peroxisomes. In the testis, peroxisomes are required in Sertoli cells, are abundant in Leydig cells (where they probably contribute to testosterone formation), and are present in germ cells but not in mature spermatozoa. The testis and spermatozoa are rich in plasmalogens and the testis contains an abundance of the peroxisomal enzymes required for plasmalogen synthesis. Mutations inactivating a single peroxisome enzyme required for either plasmalogen formation in mice or very long-chain fatty acid oxidation in humans cause impaired spermiogenesis and infertility. In fruit flies too, sperm development arrests prematurely without peroxisomes (Van Veldhoven and Baes, 2013).

Photorespiration in Green Leaves

Peroxisomes play a central role in photorespiration, a salvage pathway that rescues a 2-carbon by-product of photosynthesis. In the Calvin cycle of photosynthesis, the bifunctional chloroplast enzyme ribulose-1,5-bisphosphate carboxylase/oxygenase (RubisCO) uses its carboxylase activity to productively attach CO₂ to the 5-carbon substrate, ribulose-1,5-bisphosphate. The 6-carbon product is split into two 3-phosphoglycerate molecules, one of which goes to make glucose and the other continues through the Calvin cycle to regenerate ribulose-1,5-bisphosphate.

Figure 1 Images of peroxisomes, morphological variations. (A) HeLa cell immunofluorescence with green fluorescent protein (GFP)-labeled peroxisomes (by Gaelle Boncompain and Agathe Subtil, Institut Pasteur). (B) Rat liver electron microscopy (by Helen Shio, Rockefeller University). (a) A peroxisome with a paracrystalline core (de Duve, 1983); (b) a dumbbell-shaped peroxisome (dividing?) and (c) a peroxisome with a tubular tail (Lazarow and Fujiki, 1985). (C) Tobacco leaf electron microscopy: a peroxisome with a large trapezoidal paracrystalline core between two chloroplasts (de Duve, 1983). (D) *Saccharomyces cerevisiae* grown on glucose with GFP-labeled peroxisomes (by Richard Rachubinski, University of Alberta). (E) Mouse preputial gland, reconstruction of the elaborate peroxisome compartment within one cell from multiple serial sections (Gorgas, 1984).

However, the second activity of RubisCO, its oxygenase activity, makes mischief to varying extents, cleaving an unproductive 2-carbon molecule, glycolate phosphate, from ribulose-1,5-bisphosphate. The wasteful loss of this fragment is avoided by photorespiration, which, via an elaborate collaboration of chloroplasts, peroxisomes, mitochondria, and the cytosol, converts this glycolate phosphate into 3-phosphoglycerate to be productively metabolized in the Calvin cycle (Figure 3). Six of the key reactions, includ-

ing oxidation of glycolate to glyoxylate by an H_2O_2 -producing oxidase (see Figure 4) and transamination of the glyoxylate to glycine, occur in peroxisomes (Hu *et al.*, 2012).

Glycolysis in Trypanosomes

One of the most unusual functions sometimes found in peroxisomes is glycolysis. Glycolysis occurs in the cytosol in almost

Figure 2 Plasmalogen structure and biosynthesis. (a) Structure. (Left) conventional phosphatidyl ethanolamine, (right) the plasmalogen version of phosphatidyl ethanolamine (Boncompain *et al.*, 2014). (b) Biosynthesis – a collaborative effort of peroxisomes and ER. The reactions in the top half occur in peroxisomes, those in the bottom half in the ER. DHAP, dihydroxyacetone phosphate; DHAPAT, DHAP acyltransferase; FA, fatty acid; G3P, glycerol-3-phosphate; GPC, glycerol phosphatidyl choline; GPE, glycerol phosphatidyl ethanolamine; NADP, nicotinamide adenine dinucleotide phosphate (Wanders and Waterham, 2006a).

all organisms. The exceptional compartmentation of the glycolytic enzymes within an organelle, first discovered in *Trypanosoma brucei* (Oppenheimer and Borst, 1977), allows this parasitic flagellated protozoan to efficiently metabolize the glucose that it absorbs from the blood of its host. Originally named a glycosome, and still referred to as such, this highly specialized peroxisome has subsequently been found in other trypanosomatids and in all kinetoplastids studied (Gualdron-Lopez *et al.*, 2012). Some of these organisms are human parasites, responsible for sleeping sickness, Chagas disease, and leishmaniasis; their glycolytic enzymes are interesting as potential drug targets. Moreover, some key enzymes of glycolysis are partially localized in peroxisomes in many fungi, thanks to cryptic peroxisome targeting sequences (Freitag *et al.*, 2012).

Plugging Holes in Fungi

The Woronin body is another highly specialized type of peroxisome, which seals the septal pores of filamentous fungi in response to wounding of the plasma membrane. This avoids cytoplasmic bleeding and allows time for the cell to reseal its plasma membrane. Thus the Woronin body plays a critical

function in the maintenance of cellular integrity. It is formed by budding from conventional peroxisomes (Liu *et al.*, 2008).

Conserved Biochemical Pathways Present in Most Peroxisomes

See reviews of conserved and specialized peroxisome functions (Wanders and Waterham, 2006a; Palma *et al.*, 2009; Islinger *et al.*, 2010; Hu *et al.*, 2012).

Reactive Oxygen and Nitrogen Metabolism

Hydrogen peroxide metabolism – A simple respiratory pathway for which peroxisomes were named by Christian de Duve

Peroxisomes were first isolated from rat liver and characterized by Christian de Duve and his collaborators. The enzymes that they identified then were oxidases and catalase (de Duve and Baudhuin, 1966). The oxidases use molecules of oxygen (O_2) to oxidize uric acid, D-amino acids, and L- α -hydroxyacids with the formation of hydrogen peroxide (H_2O_2), which is then decomposed by the catalase (Figure 4). Subsequently, many

Figure 3 Photorespiration. Collaboration of four cell compartments. Metabolite abbreviations: Glu, glutamate; KG, ketoglutarate; Mal, malate; OAA, oxaloacetate; RuBP, ribulose-bisphosphate; THF, tetrahydrofolate. Enzyme abbreviations: CAT, catalase; GDC, glycine decarboxylase; GGT, glutamate:glyoxylate aminotransferase; GLYK, glycerate kinase; GOGAT, glutamate:oxoglutarate aminotransferase; GOX, glycolate oxidase; GS, glutamate synthase; HPR, hydroxypyruvate reductase; MDH, malate dehydrogenase; PGP, phosphoglycolate phosphatase; SGT, serine:glyoxylate aminotransferase; SHMT, serine hydroxymethyl transferase (Hu *et al.*, 2012).

Figure 4 Peroxisomal respiration via H₂O₂. See text for R and R' substrates (de Duve and Baudhuin, 1966).

other oxidases have been discovered in peroxisomes, acting on diverse acyl-CoAs (including very long-chain and branched fatty acyl-CoAs), polyamines, pipercolic acid, sarcosine, and, in

plants, sulfite. A methanol oxidase permits some yeast, for example, *Hansenula polymorpha* and *Pichia pastoris*, to grow on methanol as sole carbon source.

Catalase decomposes the H₂O₂ by two alternative mechanisms: the 'catalatic' dismutation of 2H₂O₂ to 2H₂O + O₂ or via the peroxidatic oxidation of substrates such as ethanol: H₂O₂ + ethanol to acetaldehyde + H₂O. The peroxidatic reaction predominates at low rates of H₂O₂ production and the catalatic reaction takes over when H₂O₂ is produced more rapidly. These enzymes constitute a simple respiratory pathway. The energy of the oxidations is not conserved in the form of adenosine triphosphate (ATP) (or otherwise) but rather is dissipated as heat.

Protection against H_2O_2 /use of H_2O_2

H_2O_2 is toxic and can damage organic molecules. Thus cells are protected by putting the enzymes that make large amounts of H_2O_2 in the same compartment with catalase that destroys it. In peroxisomes, one molecule of H_2O_2 is produced with each turn of the fatty acid β -oxidation spiral, with each cycle of photorespiration and every time an oxidase functions.

Does H_2O_2 get out of peroxisomes? Although some experiments report a substantial leakage of H_2O_2 from rat liver peroxisomes (Boveris *et al.*, 1972), others predict that not more than 2% of the H_2O_2 escapes (Poole, 1975). Catalase has first order reaction kinetics, meaning the rate of reaction is proportional to the substrate concentration: it goes faster and faster as the generation of H_2O_2 increases, without reaching a plateau. These kinetics should avoid substantial leakage. In the case of germinating seedlings, which produce substantial H_2O_2 during early growth, the peroxisomes are equipped with a second defense system against H_2O_2 , which consists of ascorbate peroxidase and monodehydroascorbate reductase (SDP2) (Hu *et al.*, 2012).

On the other hand, some H_2O_2 is useful. H_2O_2 can modify the activity of signaling molecules, for example, by oxidizing cysteine residues, thereby influencing cell proliferation, migration, and differentiation (Rhee, 2006). Cell signaling by peroxisome-derived H_2O_2 is described in both plants (Del Rio, 2011; Mhamdi *et al.*, 2012) and animals (Fransen *et al.*, 2012). H_2O_2 is also employed in cellular defense, for example, in pathogen killing by neutrophils, where it is compartmentalized within phagosomes.

Other reactive oxygen and nitrogen species

Other reactive oxygen and nitrogen species are produced in peroxisomes. Xanthine oxidase in mammalian peroxisomes makes superoxide (O_2^-) as well as H_2O_2 and can reduce nitrates and nitrites to nitric oxide (NO). The inducible form of NO synthase is partly localized in peroxisomes and makes both O_2^- and NO. Hydroxyl radicals ($\bullet OH$) are formed non-enzymatically by the Fenton reaction between H_2O_2 and Fe^{2+} . In plants, NO and S-nitrosoglutathione are found in peroxisomes and may contribute to signaling, for example induction of defense genes by nitrosoglutathione. These reactive compounds affect the redox state within peroxisomes and, indirectly, that of other cell compartments.

Peroxisomes also contain enzymes that protect against reactive oxygen and nitrogen species, including superoxide dismutase, peroxiredoxin 5, glutathione S-transferases, and epoxide hydrolase as well as catalase. The balance between production and destruction of reactive oxygen and nitrogen molecules, in different cells and tissues, under different physiological and pathological conditions, determines the positive and negative results.

Fatty Acid β -Oxidation

A highly conserved pathway of fatty acid β -oxidation is found in almost all peroxisomes (Figure 5(a)). In plants, the peroxisome is the sole organelle capable of this catabolism. This is also true in many fungi (*Saccharomyces cerevisiae*, *Candida tropicalis*, *P. pastoris*, and *Yarrowia lipolytica*), which use these

peroxisomal reactions to grow on fatty acids. However, a bioinformatics analysis of 57 fungal species for which complete genome sequences were available showed that other fungal species also contain the genes for a second β -oxidation system in their mitochondria (Shen and Burger, 2009).

In animals, mitochondrial β -oxidation was well known long before peroxisomal β -oxidation was discovered. We now know that the pathway occurs in both organelles, but with different specificity, different regulation, and different gene products. Mammalian peroxisomes not only oxidize the usual long-chain fatty acids, but in addition oxidize a variety of substrates that the mitochondrial β -oxidation cannot: very long-fatty acids (i.e., C24, C26, and up), branched-chain fatty acids, and polyunsaturated fatty acids. Peroxisomal β -oxidation participates in the anabolic (biosynthetic) formation of bile acids by shortening the side chain of cholesterol. Peroxisomes oxidize about one-third of the palmitic acid in rat liver (Kondrup and Lazarow, 1985). If the peroxisomal pathway is defective, many of its substrates accumulate with toxic consequences.

Mitochondrial β -oxidation is coupled to oxidative phosphorylation and is well-adapted to generate ATP. The acetyl-CoA that is formed can be further oxidized in the Krebs cycle to make more ATP. In contrast, peroxisomal β -oxidation dissipates some energy as heat and the acetyl-CoA formed is likely used for biosynthetic purposes. In plants, protozoa and fungi, it is often used for gluconeogenesis via the glyoxylate cycle. In animals, it may be used for the synthesis of cholesterol and steroids and in fungi is used to make polyketide toxins.

The enzymes that catalyze the four reactions of the β -oxidation spiral in peroxisomes are distinct from their mitochondrial counterparts (Figure 5(a)). The first peroxisomal reaction produces H_2O_2 ; a variety of oxidases with different substrate specificities catalyze this reaction. The next two reactions are catalyzed by a bifunctional enzyme (there are two such enzymes with different stereochemistry) and the fourth reaction is catalyzed by several thiolases, again with differing substrate specificities. Additional enzymes are involved: ligases that conjugate substrates to Coenzyme A, a racemase, isomerases, carnitine transferases, and membrane transporters that bring in acyl-CoAs and export products (Figure 5(b)). Altogether, 17 gene products are involved in humans, not counting transporters (Wanders and Waterham, 2006a).

The Glyoxylate Cycle and Glyoxylate Metabolism

The glyoxylate cycle allows 2-carbon compounds to be converted to a 4-carbon molecule, succinate, which in turn can be converted to sugar or to amino acids or can replenish the Krebs cycle. This permits *de novo* gluconeogenesis from fatty acids, which occurs in some plant tissues (as described earlier for germinating seedlings) and in protozoa and fungi. It also allows the utilization of ethanol and acetate as sole carbon sources by yeasts. The two key enzymes of the cycle attach acetyl-CoA first to glyoxylate (to form malate, which is oxidized to oxaloacetate) and then to oxaloacetate (to form citrate). In the last step, isocitrate is cleaved to produce the product, succinate, and reform glyoxylate, for which the cycle is named (Figure 6(a)).

Figure 5 Peroxisomal fatty acid β -oxidation. (a) Principal reactions (Lazarow and de Duve, 1976). (b) Auxiliary reactions for diverse substrates (Wanders and Waterham, 2006a).

Formerly it was thought that all five enzymes of the cycle are located together inside peroxisomes (also called 'glyoxysomes'). In fact, only the two key enzymes, the malate and

citrate synthases, are always inside peroxisomes, which permits them to utilize directly the acetyl-CoA produced by β -oxidation (Kunze *et al.*, 2006). The malate dehydrogenase and

Figure 6 Glyoxylate cycle. (a) Reactions. Enzyme abbreviations: ACO, aconitase; CIT, citrate synthetase; ICL, isocitrate lyase; MDH, malate dehydrogenase; MLS, malate synthetase. (b) Compartmentation (Kunze *et al.*, 2006).

aconitase and sometimes the isocitrate lyase are found outside, in the cytosol (Figure 6(b)). This may serve to protect them from damage by H_2O_2 , to which some are sensitive, but it requires the efficient transport of the cycle intermediates into and out of the peroxisomes.

Mammals lack the glyoxylate cycle altogether (despite a few claims to the contrary) but glyoxylate is nevertheless produced by peroxisomal glyoxylate oxidase, and converted to glycine by an aminotransferase. Failure to do this conversion causes hyperoxaluria type 1 – details below.

Other Peroxisome Functions

Polyamine Catabolism

The conversion of spermine to spermidine and then to putrescine occurs in peroxisomes in both animals and plants.

Purine Catabolism

Most mammals and some plants degrade purines to allantoin (by means of xanthine oxidase and urate oxidase); other organisms degrade allantoin further to urea and glyoxylate. Urate oxidase is peroxisomal in both vertebrates and plants (e.g., *Arabidopsis thaliana*) but has been lost altogether in primates, making us susceptible to gout.

Fatty Acid α -Oxidation

Some fatty acids (e.g., with a methyl group on the 3rd carbon) require α -oxidation before entering the β -oxidation spiral. An

example is dietary phytanic acid (some of which is derived from chlorophyll). Peroxisomes are the unique site of this α -oxidation.

Bile Acid Synthesis

Peroxisomes catalyze the last steps in bile acid synthesis, including a β -oxidative shortening of the side chain of cholesterol.

Cholesterol, Steroids, Isoprenoids, and Wax Ester Synthesis

Peroxisomes are very abundant in cells and tissues that synthesize cholesterol, steroids, isoprenoids, and wax esters, suggesting the possibility that they participate in these metabolic pathways. There are differences of opinion on whether the enzymes of cholesterol biosynthesis are located in peroxisomes. It is certain that peroxisomes can make the long-chain alcohols that are found in wax esters.

Biotin Synthesis

Plants and some fungi synthesize biotin; the first steps require peroxisomes and the later steps occur in mitochondria (Maruyama *et al.*, 2012).

Fungal Sex

Great diversity is observed in the sexual reproduction of fungi. Mechanisms of meiosis, formation of reproductive structures, mating, germination, and dispersal of spores and mobilization of energy reserves to support these processes all vary. Peroxisomes are involved in many different ways (Peraza-Reyes and Berteaux-Lecellier, 2013).

Signaling

Peroxisomes contribute to the synthesis and/or degradation of signaling molecules in both plants and animals. For example, leukotrienes and prostaglandins are degraded by peroxisome β -oxidation.

Plant hormones (phytohormones)

Auxins (primarily indole-3-acetic acid) regulate cell growth and cell division and affect many aspects of plant development, including root system development and stamen elongation. Jasmonates (derived from fatty acids) regulate the response to stresses (e.g., wounding or infection by pathogens) and also affect plant development. Both jasmonates and auxins require peroxisomes for their synthesis, primarily utilizing peroxisomal enzymes of β -oxidation.

Platelet activating factor

Platelet activating factor (1-O-alkyl-2-acetyl-sn-glycero-3-phosphocholine) potentially mediates diverse intercellular interactions. It signals leukocyte activation in inflammation, is involved in allergic reactions and aggregates platelets to arrest bleeding. It is an alkyl phospholipid, similar to the plasmalogens described above, and thus requires peroxisomes for its

Figure 7 Chlamydia (blue) growing inside an inclusion body in human cells with some peroxisomes (red) imported into the inclusion; GFP in the cytosol (Boncompain *et al.*, 2014).

synthesis. However, most platelet activating factor is rapidly made when needed by the remodeling of preexisting alkyl phospholipids: an arachidonoyl moiety is removed by a specific phospholipase and replaced with an acetyl group; these reactions occur downstream from the initial formation in peroxisomes.

Pathogen Defense and Pathogen Offense

Exploitation of peroxisomes by a bacterium, *Chlamydia trachomatis*

Chlamydia trachomatis, an obligate intracellular pathogen that is responsible for loss of eyesight and sexually transmitted diseases, exploits many parts of the human host cell, including peroxisomes. The bacteria develop within a membrane-bounded inclusion; remarkably they cause peroxisomes to enter inside this inclusion (Figure 7). The growing bacteria incorporate plasmalogens and some of these plasmalogens contain bacteria-specific odd-chain fatty acids, indicating a metabolic collaboration of peroxisomes and bacteria for their formation (Boncompain *et al.*, 2014).

Antibiotic synthesis by fungi

Penicillin and cephalosporin, two β -lactam antibiotics that have been invaluable in defending humans against diverse pathogens, are synthesized in *Penicillium chrysogenum* by a collaboration of cytosolic enzymes with enzymes inside peroxisomes. The peroxisomal enzymes that help make penicillin, acyl-CoA ligases, and acyl-transferase, belong to the family of fatty acid metabolizing enzymes. The location of this part of the pathway within the organelle is important: in cells with

aberrant or missing peroxisomes, much less penicillin is produced. The fungal peroxisomal epimerases of cephalosporin synthesis have remarkable sequence similarity to mammalian peroxisomal enzymes involved in bile acid synthesis, and are related to peroxisomal enzymes of branched-chain fatty acid metabolism (Martin *et al.*, 2012).

Toxin synthesis by fungi

Aspergillus species aggress plants with polyketide mycotoxins, for example, aflatoxin, that are synthesized from acetyl-CoA produced in peroxisomes. The AK-toxin that attacks Japanese pears is made by peroxisomal enzymes.

Plant immune defense against fungi

In *Arabidopsis*, a peroxisomal glycosyl hydrolase (PEN2) is part of the innate immune response and is essential to the defense against noninvasive (nonadapted) fungal pathogens. Its activity and its localization within peroxisomes are both essential (Lipka *et al.*, 2005). Jasmonate signaling, mentioned above, mediates plant defense against necrotrophic pathogens.

Mammalian immune defense against viruses

Peroxisomes play an important role in mammalian immune defense against viruses. RIG-I-like receptors, which are soluble RNA helicases, detect viral RNA in the cytosol. These receptors then interact with the mitochondrial antiviral signaling (MAVS) protein that is located on both peroxisomal and mitochondrial membranes (Figure 8). The peroxisomal MAVS signals the cell to switch on an immediate and rapid antiviral response. In complementary fashion, the mitochondrial MAVS signals, via interferon production, a slower but sustained antiviral response. Both are necessary: for example, vesicular stomatitis virus can interfere with and escape the interferon-mediated response, but is susceptible to the fast peroxisome-mediated response. The peroxisomal response is accompanied by a striking change in morphology, with aggregation and the formation of peroxisomal tubules (Dixit *et al.*, 2010).

Exploitation of peroxisomes by viruses

Tombusviruses replicate their single-stranded RNA genome in invaginations of the peroxisomal membrane within plant cells. Rotavirus targets its spike protein, VP4, to peroxisomes. Other viral proteins interact with peroxisomal proteins, for example, HIV's Nef and influenza's NS1. It appears likely that the viruses exploit the lipid metabolism of peroxisomes, but further studies are necessary to elucidate these intriguing observations (Lazarow, 2011).

Metabolic Cooperation and Interaction with Other Organelles

For 40 years, peroxisomes have been observed in close physical proximity to other organelles, including lipid droplets, endoplasmic reticulum (ER), mitochondria, and chloroplasts (Figure 9). Apposition of the membranes facilitates transfer and exchange of metabolites and supports the multiple metabolic collaborations among these organelles: peroxisomes and lipid droplets for fatty acid metabolism in seedlings and adipocytes; peroxisomes and the ER to synthesize plasmalogens;

Figure 8 Peroxisome role in immune defense. Viral RNA in mammalian cells is detected by RIG-I and signaled to MAVS on peroxisomes and on mitochondria. The peroxisomal MAVS switches on a signaling pathway that produces a rapid antiviral response. Complementarily, mitochondrial MAVS uses other signaling pathways to produce interferon- β and a sustained antiviral response (Dixit *et al.*, 2010). JAK, janus kinase; STAT, signal transducer and activator of transcription.

peroxisomes, chloroplasts, and mitochondria in photorespiration; and peroxisomes, mitochondria, and the cytosol in gluconeogenesis. Peroxisome and mitochondria are further linked by shared functions in reactive oxygen metabolism and the acetyl-CoA formed in peroxisomes can be further oxidized via the Krebs cycle in mitochondria. Fission and inheritance of these two organelles share some common factors and vesicles produced from mitochondria can target peroxisomes. Moreover, there is reciprocal regulation: retrograde signaling of the mitochondrion to the nucleus causes a marked proliferation of peroxisomes in *S. cerevisiae* and defects in one have been shown to produce changes in the other (Thoms *et al.*, 2009). The old morphological observations of proximity have been refined recently by high-throughput genetic screens, which found that peroxisomes are located near two specific subdomains of mitochondria: one enriched in the pyruvate dehydrogenase complex and another that is the point of contact of mitochondria with ER (Cohen *et al.*, 2014). The screens also identified

mutants in which peroxisome membranes are assembled but matrix enzymes are not imported – these are the peroxisomal membrane ghosts first identified in Zellweger syndrome (Santos *et al.*, 1988b) – see human diseases below.

Peroxisome Abundance, Adaptability, and Regulation

The peroxisome population in cells is dynamic and its abundance and form is the result of multiple interacting processes: rate of formation (influenced by environmental factors via transcriptional regulation), division (affecting size, number, and shape), transport and segregation into daughter cells, and turnover by autophagy.

Abundance and Adaptability

One of the remarkable things about peroxisomes is their ability to adapt in abundance and enzymatic capability to

Figure 9 Peroxisome interactions with other organelles. (A) With lipid bodies. (a) In *S. cerevisiae*. LB, lipid droplet; P, peroxisome (Binns *et al.*, 2006); (b) in tomato seedling (de Duve, 1983). (C) With mitochondria (m) and chloroplasts (c) in *Arabidopsis*. (Kaur *et al.*, 2009).

different circumstances. Diet, drugs, light, and temperature all influence the peroxisome population, along with the developmental needs of the organism.

An example is the yeast, *H. polymorpha*: it contains one or a few tiny peroxisomes when grown on glucose. Shift it to methanol medium and large peroxisomes develop with a new complement of enzymes adapted to methanol assimilation (Figure 10(A)). *Saccharomyces cerevisiae* adapts to a shift from glucose medium to oleic acid medium by a proliferation of peroxisomes containing upregulated β -oxidation enzymes. *Pichia pastoris* peroxisomes adapt appropriately to either methanol or fatty acids in the medium.

Light influences plant development and differentiation. When *Arabidopsis* is exposed to light and begins photosynthesis, peroxisomes that were oxidizing fat adapt to do photorespiration. Reactive oxygen species, UV radiation, and salt stress also induce plant peroxisome proliferation.

Fungi adapted to produce large amounts of penicillin have more peroxisomes than other strains (Figure 10(B)).

Cold temperatures induce peroxisomes in brown fat, a site of thermogenesis, and in some fishes, probably be-

cause peroxisomal oxidative metabolism dissipates energy as heat.

Many hypolipidemic drugs cause a striking proliferation of peroxisomes in rat liver (Figure 10(C)), an observation that led to the discovery of β -oxidation in animal peroxisomes (Lazarow and de Duve, 1976). Peroxisomal β -oxidation activity and peroxisome abundance are induced as much as 10-fold by these drugs.

Gene Regulation

Transcription factors control these responses (Schrader *et al.*, 2012; Figure 10(D)). In *S. cerevisiae*, two proteins with fatty acid-binding domains, Pip2 and Oaf1, form a heterodimer and switch on genes with oleate response elements. An additional zinc finger protein that senses carbon status, Adr1, and a kinase, Snf1, also participate. In a filamentous fungus, *Aspergillus nidulans*, FarA and FarB bind fatty acids and do the job.

In *Arabidopsis*, a photoreceptor, phytochrome A, translocates into the nucleus when stimulated by far red light and

Figure 10 Continued.

interacts with transcription factors, for example, HYH, to switch on genes.

In mammals, the receptor for unsaturated long-chain fatty acids and hypolipidemic drugs is PPAR α (peroxisome proliferator activated receptor- α). It is in the class of steroid and retinoid receptors and dimerizes with RXR α (retinoid X receptor- α) to form the active DNA-binding transcription factor that upregulates a variety of genes, including the peroxisomal β -oxidation genes.

Peroxisome Division, Transport, and Inheritance

Peroxisome Division

Peroxisomes proliferate and divide by a conserved process, usually consisting of elongation or tubulation followed by constriction and fission (Saraya *et al.*, 2010; Schrader *et al.*, 2012; Figure 11(A)). The progeny may have the same size and composition or the daughter peroxisome may be smaller than the mother peroxisome (Figure 11(B)). Some membrane proteins may appear preferentially in the elongation and some matrix enzymes may be retained in the mother peroxisome, resulting in an asymmetric division of the content. An extreme example of asymmetric division is the formation of Woronin

bodies by budding from a conventional peroxisome (Figure 11(C)). Peroxisome division is controlled and catalyzed by two families of proteins, Pex11 proteins (specific to peroxisomes) and dynamin-related proteins (large GTPases with diverse roles in cell membrane fission and fusion).

Pex11 controls peroxisome proliferation and abundance: it is physiologically upregulated when peroxisomes are induced and its experimental overexpression produces many more, smaller peroxisomes. If knocked out, there is generally one or a few of the organelles. In *S. cerevisiae*, Pex11's activity is regulated by phosphorylation. Many organisms have several Pex11-related proteins with somewhat different functions. In the case of *Arabidopsis* there are five: overexpression of Pex11c causes tubulation; overexpression of Pex11e doubles the number of peroxisomes without visible elongation (Figure 11(D)).

Pex11(s) catalyze the first steps in division. It contains amphipathic helices that insert into the peroxisome membrane and cause bending that results in the elongation of the membrane. Pex11 then accumulates at or near the site where fission will occur and probably helps to recruit other proteins there, for example, Fis1, an integral membrane protein that anchors the protein(s) that catalyze fission.

The next steps, constriction and scission, are catalyzed by the dynamin-like proteins (DLP): Dlp1 in mammals, Dnm1

Figure 11 Peroxisome division. (A) Model of division. (a) membrane bending and elongation via Pex11 insertion; (b) constriction and scission by DLP with the energy of GTP hydrolysis (Schrader *et al.*, 2012). Figure 11 Continued.

and Vps1 in yeast, and several DRP isoforms in plants. They are recruited to the fission site by Fis1 and other auxiliary proteins and form a ring around the membrane elongation (Figure 11(A)). Remarkably, the same mechanism is used for other organelles: Vps1 also catalyzes mitochondrial fission and DRP5B also catalyzes chloroplast fusion. Defects in scission cause a variety of results, including fewer but larger peroxisomes or sometimes an elongated, partially divided peroxisome poised between mother and daughter in budding yeast (Figure 11(E)).

Peroxisome Fusion?

In contrast to mitochondria, peroxisomes appear not to fuse; certainly they lack the machinery used by mitochondria for this purpose. Experiments mixing *in vivo* peroxisomes labeled differently failed to detect any mixing of their contents (Huybrechts *et al.*, 2009). This suggests that the elaborate interconnected peroxisome networks in the preputial gland (Figure 1(E)) are due to a lack of fission rather than to fusion, or else that fusion is possible in certain cell types or under special metabolic circumstances (Schrader *et al.*, 2012).

Inheritance of Peroxisomes – Tethering and Guided Transport

When budding yeast divide, elaborate mechanisms ensure that the growing bud, and hence the daughter cell, receives all the cell organelles: at least one mitochondrion, some ER and Golgi, etc. Peroxisomes are transported along actin cables into the bud, pulled by the class V myosin motor, Myo2, which is attached to the peroxisomal membrane by the Inp2 protein (Fagarasanu *et al.*, 2010). Other peroxisomes remain in the

mother cell, firmly anchored in place by the Inp1 protein, which is attached to the peroxisomal integral membrane protein Pex3 (Figure 12). If transport is defective, cytokinesis is delayed. Coordination between anchoring and transport ensures appropriate partitioning of the organelle. In the case of impaired fission, one sometimes sees the partially divided peroxisome straddling the gap between the two cells (Figure 11(E)); eventually the peroxisome is pulled into two parts and the cell divides.

When mammalian cells divide, their large number is probably sufficient to partition the organelles into both daughter cells stochastically, but nevertheless there is also active transport along the cytoskeleton. One of the few big changes in peroxisome biology during evolution is that the peroxisome moves on microtubules in animals and on actin cables in yeast and plants.

Peroxisome Biogenesis

Historical Perspective

Peroxisome biogenesis has some unique features, not seen in other organelles. It has no DNA and synthesizes none of its own proteins. Our understanding of its biogenesis has changed several times and continues to evolve; some aspects remain uncertain and/or controversial.

Model 1: Formation from ER

In 1973, it was "almost textbook knowledge that peroxisomes arise as budding outgrowths of the ER. Their proteins are believed to be synthesized on membrane-bound ribosomes, to be delivered intraluminally and to be conveyed to the growing peroxisomes through ER channels" (de Duve,

Figure 12 Model of organelle transport and inheritance via class V myosin motors in *S. cerevisiae*. Some peroxisomes travel to the bud while others remain anchored in the mother cell (Fagarasanu *et al.*, 2010).

1973; Figure 13(a)). This theory, that all peroxisome enzymes pass through the ER, as do secretory proteins, was based largely on electron microscopic studies of Novikoff and Shin (1964).

Model 2: Growth and division

The discovery that catalase never enters the ER but instead is imported directly into preexisting peroxisomes *in vivo* challenged this view (Lazarow and de Duve, 1973; Figure 13(b)). Subsequent experiments on peroxisomal proteins in animals, plants, and fungi gave similar results: many enzymes and a major membrane protein were made on free polyribosomes and released into the cytosol and could be imported into purified peroxisomes *in vitro*. Review of these data led to the hypothesis that peroxisomes form by growth and division, importing enzymes, and membrane proteins directly from the cytosol (Lazarow and Fujiki, 1985; Figure 13(b)). This model, with one important modification, a contribution of the ER to membrane growth, has been robustly confirmed by 25 years of molecular cell biology (Rucktaschel *et al.*, 2011; Nuttall *et al.*, 2011; Ma *et al.*, 2011; Dimitrov *et al.*, 2013; Smith and Aitchison, 2013; Fujiki *et al.*, 2014; Hettema *et al.*, 2014). The details continue to be refined.

Model 3: De novo membrane formation

The appearance of peroxisomes in mutant cells that appear to lack the organelle (see details below) implied the *de novo* formation of peroxisomes, with the membrane coming from the ER, followed by maturation as in model 2 (Figure 13(c)). Experiments testing the extent of the ER contribution to peroxisome biogenesis under physiological conditions have produced conflicting results and controversy, and research continues to address this question.

Current Model: Growth and Division with Some Help from the ER

Thirty-three 'PEX' genes have been identified whose products, 'peroxins,' (denoted here as Pex1, Pex2, etc.) catalyze peroxisome biogenesis (Table 1). Nineteen collaborate in the translocation of enzymes from the cytosol through the peroxisome membrane into the lumen of the organelle. Only three catalyze membrane protein assembly. The rest are involved in proliferation and division (Figures 14 and 15).

Targeting and import of soluble enzymes into peroxisomes

Two types of targeting sequence can direct peroxisome enzymes to their organelle: a C-terminal tripeptide (SKL and variants thereof) or an N-terminal nonapeptide (RLxxxxx(H/Q)I and variants thereof). These targeting sequences are recognized by soluble recycling receptors, Pex5 and Pex7, respectively, that bind the newly synthesized proteins in the cytosol and transport them to peroxisomes. The translocation machinery consists of a docking complex, a transient pore, and a complex to reexport the recycling receptor, driven by ubiquitinylation and ATP hydrolysis (Hettema *et al.*, 2014). Remarkably, the pore can accommodate folded and oligomerized proteins. It even allows a few proteins without targeting sequences to enter 'piggyback,' i.e., bound to a properly targeted protein. Pex5 forms part of the dynamic pore (Meinecke *et al.*, 2010), whereas Pex7 can pass inside the organelle and then be reexported (Nair *et al.*, 2004). The tripeptide targeting sequence is retained in the mature imported enzymes; the N-terminal sequence is often cleaved in plants but usually retained in animals and yeasts.

Direct targeting and insertion of peroxisome membrane proteins into peroxisomes

Most membrane proteins are targeted to existing peroxisomes by internal sequences consisting of a cluster of positively

Figure 13 Peroxisome biogenesis – historical models. (a) Budding fully formed peroxisomes from the ER. (b) Growth and division. (c) *De novo* membrane formation in the ER. Numbers indicate Pex gene products.

charged amino acids near a transmembrane domain. These 'Class 1' proteins are recognized by a soluble, cytosolic, recycling receptor, Pex19, which also functions as a chaperone. Pex19, carrying its cargo, docks on the peroxisome integral membrane protein, Pex3, and the newly synthesized protein inserts into the membrane. In mammalian cells, a second integral membrane protein is required, Pex16, which recruits Pex3 to the membrane ('Class 2'). Thus far, no other components have been found necessary for membrane protein assembly. Membrane growth does not require functioning import machinery; when import is defective, membranes continue to grow and divide as empty peroxisome 'ghosts' (Santos *et al.*, 1988b; Figure 16(A)).

Modification of the model: ER contribution to peroxisome membrane growth

There is now good evidence for a second mechanism by which several membrane proteins reach peroxisomes: insertion in the ER followed by travel in vesicles to existing peroxisomes (Figure 14). In *S. cerevisiae*, epitope-tagged Pex3 expressed from a strong promoter moves from ER to

existing peroxisomes (as well as to new peroxisomes – see below) (Hoepfner *et al.*, 2005). Budding from the ER of vesicles carrying Pex3 and Pex15 has been demonstrated in a cell-free assay (Lam *et al.*, 2010). The budding reaction requires Pex19 and ATP and unknown cytosolic proteins, and is distinct from the budding of vesicles carrying secretory proteins. This vesicle traffic occurs physiologically: a multiply-tagged version of Pex15 with an engineered N-glycosylation site arrives in peroxisomes in wild type *S. cerevisiae* mostly glycosylated, indicating transit through the ER.

Pex3 also inserts directly into peroxisomes at Pex16 docking sites (Matsuzaki and Fujiki, 2008; Aranovich *et al.*, 2014), clearly indicating that it has two independent, redundant pathways to reach its organelle.

In several plant species, the normal physiological route of the APX membrane protein is first into ER and then by vesicle transport to peroxisomes, whereas other membrane proteins insert directly from the cytosol into peroxisomes (Mullen and Trelease, 2006). Thus, also in plants, peroxisome membrane growth occurs by two mechanisms.

Table 1 PEX genes, peroxin functions and human disease complementation groups

Process	Gene	Protein function	Notes	Human disease complementation group
Transport of newly synthesized enzymes through the cytosol to peroxisomes:				
PTS receptors	Pex5	Shuttling receptor for PTS1 proteins	Bifunctional amphipathic protein; coreceptor for Pex7 in mammals	US/EU 2
Co-receptors	Pex7	Shuttling receptor for PTS2 proteins	Recycles from peroxisome interior	11
	Pex18	Co-receptor for PTS2 proteins in <i>Saccharomyces cerevisiae</i>		
	Pex21	Co-receptor for PTS2 proteins in several yeasts	Structurally similar	R
	Pex20	Co-receptor for PTS2 proteins in other fungi		
Translocation of newly synthesized enzymes into peroxisomes:				
Receptor docking complex	Pex13	Site for shuttling receptors to dock on exterior of membrane	Membrane protein	13

There are conflicting data on the extent of the ER contribution and which proteins use this route. Affinities and kinetics may explain some of the differing results. Neither Pex3 nor Pex16 are seen in ER in wild type cells, but they appear there when over-expressed. If these proteins pass quickly

through the ER this could explain why they are not observed there physiologically. Or, if they normally enter peroxisomes, but the peroxisomes have a limited capacity to integrate them, this would explain the ER overexpression results. If vesicles coming from the ER transit rapidly to mature peroxisomes, they will simply donate membrane components to the peroxisomes. If the vesicles bearing Pex3 spend a long enough time in the cytoplasm, they could gradually acquire the other membrane proteins necessary for importing enzymes, and mature without fusion (see *de novo* formation below). If peroxisome membrane proteins reside long enough in the ER in some cell types, they could create specialized regions enriched in peroxisome proteins.

It is clear that there are two functional pathways for peroxisome membrane protein assembly. It is not certain whether they are fully redundant or if collaboration of the two pathways is required. More research on proteins expressed normally in wild type cells will clarify the physiological process.

Phospholipids

Since most phospholipids are synthesized in the ER, it was speculated that they are brought from the ER to growing peroxisomes by vesicular transport (Lazarow and Fujiki, 1985). This is indeed a function that can be provided by the vesicle traffic that has now been observed. This mechanism does not exclude additional vesicle-independent phospholipid transport at ER-peroxisome contact sites (Raychaudhuri and Prinz, 2008). Additional information on the quantitative contribution of each mechanism to lipid transport is desirable.

De novo Formation of Peroxisome Membranes from the ER

Evidence for de novo formation in mutants

A mutation in PEX3, PEX16, or PEX19 prevents the assembly of (most) membrane proteins, and causes the apparent disappearance of peroxisomes. Genetic complementation of the mutants results in the reappearance of peroxisomes. This process occurs by two distinct steps: first recognizable peroxisome membranes (similar to ghosts) gradually accumulate, and then they fill up with enzymes (Figure 13(c)); this takes several days in mammalian cells and several hours in yeast.

From where do the membranes arise in these mutants? In *S. cerevisiae*, Pex3 inserts into the ER and then appears in vesicles (Hoepfner *et al.*, 2005). In mammalian cells Pex16 inserts in the ER, recruits Pex3 and forms vesicles (Kim *et al.*,

Figure 16 Peroxisomes in mutants. (A) Peroxisome membranes ('ghosts') in Zellweger patient cells. (a) Fluorescence microscopy: peroxisomes appear to be absent with an antibody against catalase, a luminal enzyme (top row); however, an antibody against peroxisome membrane proteins reveals the membranes, which are larger in size and fewer in number than normal (bottom row) (Santos *et al.*, 1988b). (b) Electron microscopy identifying peroxisome membrane ghosts with an electron dense cytochemical reaction product (arrows). M, mitochondrion (Santos *et al.*, 1988a). (B) Pre-peroxisome vesicles ('remnants') in *H. polymorpha* pex3/atg1 double mutant cells. 3D reconstruction of the vesicles (black arrows) and reticular structures (red arrows), which contain Pex8, Pex13, and Pex14 as well as a little Pex5 and alcohol oxidase enzyme. N, nucleus; V, vacuole (Knoops *et al.*, 2014).

2006). The consensus view is that these ‘pro-peroxisome’ vesicles then recruit the other peroxisome membrane proteins by the usual method from the cytosol, become translocation competent, and import the peroxisome enzymes, thus maturing into new peroxisomes. A minority view is that all the peroxisome membrane proteins pass through the ER and never fuse with older peroxisomes (van der Zand *et al.*, 2010, 2012).

De novo formation physiologically?

Whether and to what extent *de novo* peroxisome formation occurs in normal cells is the subject of ongoing debate and may be greater in mammals than in fungi or plants. Experiments with peroxisome-targeted photo-activatable green fluorescent protein (GFP) detected both peroxisome division and *de novo* peroxisome formation in cultured rat kidney epithelial cells, with about 70% *de novo* formation (Kim *et al.*, 2006). Subsequent work confirms the functioning of the two pathways, but shows that the exogenous expression of Pex16-mCerulean in the previous work may have exaggerated the ER role (Aranovich *et al.*, 2014). In contrast, peroxisomes are thought to form largely by asymmetric division in CHO cells (Huybrechts *et al.*, 2009). When peroxisome division is blocked in *H. polymorpha*, one large peroxisome is seen, implying that division is the major pathway in this species (Nagotu *et al.*, 2008). Pulse-chase and mating assays in wild type *S. cerevisiae* clearly showed that the ER supplies membrane components to existing peroxisomes, but no *de novo* formation occurred (Motley and Hettema, 2007). This conclusion was confirmed by fluorescence tagging experiments (Menendez-Benito *et al.*, 2013). Likewise, *de novo* formation has not been detected in any plant, but the ER does supply membrane proteins to existing organelles (Mullen and Trelease, 2006).

Doubts about de novo formation

The concept of *de novo* formation from the ER in yeast is challenged by the recent discovery using electron tomography that peroxisome-related structures are not, in fact, entirely

absent in PEX3 knockout strains of *H. polymorpha* and *S. cerevisiae* as had been thought; in fact small vesicles and tubules exist that contain Pex8, Pex13, and Pex14 as well as a little Pex8 and alcohol oxidase (Figure 16(B); Knoops *et al.*, 2014). Similar peroxisomal ‘remnants’ were detected previously in PEX3 and PEX19 knockouts of *P. pastoris* (Hazra *et al.*, 2002) but largely ignored. When Pex3 is reintroduced in *H. polymorpha*, it goes to these little structures, not to the ER, and peroxisomes are reformed gradually from them (Knoops *et al.*, 2014). The origin of these vesicles and tubules is not certain: if they are remnants of old peroxisomes from before the knockout, the peroxisomes have been rescued, as suggested previously (Lazarow, 2003), rather than made *de novo*. If they are not remnants, our understanding of *de novo* formation must change. These tiny structures are located adjacent to the ER and might not have been resolved by routine fluorescence microscopy in previous studies.

Remodeling, Random Turnover, and Selective Degradation

In most organisms, the steady growth in peroxisomes is counterbalanced by a steady, random autophagic degradation (Oku and Sakai, 2010; Saraya *et al.*, 2010). In rat liver, catalase and other peroxisome proteins turnover with exponential decay kinetics and a half-life of 1.5 days; these kinetics imply random destruction of the organelle (Poole, 1969). Forty years later, similar results (exponential decay, 2-day half-life) were obtained with entirely different methods on cultured CHO cells (Huybrechts *et al.*, 2009).

Peroxisomes are also selectively destroyed, when appropriate, by targeted autophagy, termed ‘pexophagy’ (Figure 17). For example, peroxisomes are induced in methylotrophic yeast by growth on methanol; withdrawal of this carbon source and addition of glucose causes these peroxisomes to be autophagocytosed and degraded. Similarly, withdrawal of a

Figure 17 Autophagy of peroxisomes (‘pexophagy’). Top, macropexophagy, PAS=pre-autophagosomal structure; bottom, microautophagy, MIPA=micropexophagic membrane apparatus (Oku and Sakai, 2010).

hypolipidemic drug from mammals leads to pexophagy of the excess peroxisomes. In green leaves, peroxisomes damaged by H_2O_2 aggregate and are selectively degraded (Shibata *et al.*, 2014).

The functional remodeling of plant peroxisomes from fat metabolism to photorespiration upon greening is accomplished in part by a change in gene regulation (Mullen and Trelease, 2006): turn off one set of genes and turn on the other and in two half-lives three-fourth of the enzymes will be the new ones. In addition, plants help remodeling by selective autophagy (Kim *et al.*, 2014).

Evolution

Peroxisomes have been found in all five branches of the eukaryotic tree of life, although the vast majority of our knowledge concerns two branches, the Unikonts, containing animals and fungi, and the Plantae (Gabaldon, 2010). The mechanisms of peroxisome biogenesis and division are universally conserved, even among the peroxisomes with the most exceptional functions. Almost all peroxisomes harbor the enzymes of reactive oxygen metabolism and β -oxidation, strongly supporting a common evolutionary origin. Protection against H_2O_2 would have been useful to primitive aerobic organisms (de Duve and Baudhuin, 1966). Peroxisomes may be the descendants of an ancient endosymbiont that later lost all of its DNA while retaining a posttranslational type of protein import (topologically like mitochondria and chloroplasts but mechanistically different) (de Duve, 1969). However, the eukaryotic origin of the proteins that catalyze peroxisome biogenesis (Figure 18(A)) and the homology of some to the ER-associated decay (ERAD) pathway (Figure 18(B)) suggest an ER evolutionary origin for the membrane of the organelle (Schluter *et al.*, 2006; Gabaldon *et al.*, 2006). This would be consistent with new peroxisome membrane formation from the ER. The remarkable present diversity of peroxisomal enzymatic capabilities is likely due to the acquisition of enzymes and enzyme pathways retargeted from other cell compartments during evolution, which could have been accomplished by simply equipping them at their carboxy-terminus with the tripeptide that targets proteins to peroxisomes.

Human Disease and Peroxisomes

Defects in peroxisome biogenesis (Steinberg *et al.*, 2006) or function (Wanders and Waterham, 2006b) cause devastating human disease. Pathologists were aware of some of these diseases before much was known about peroxisomes. When (Goldfischer *et al.*, 1973) observed that peroxisomes were missing in the liver and kidney of two Zellweger syndrome neonates, the absence of the known enzymes could not explain the severe developmental neuropathology. This implied that the peroxisome had important other capabilities to be discovered and prompted a wave of productive research. The subsequent discovery that Zellweger cells contain peroxisome membrane ghosts (Santos *et al.*, 1988b) suggested that the

disease was due to a defect in biogenesis, specifically in the import of matrix enzymes, and stimulated further research.

Fourteen genetic complementation groups of Zellweger patients have been identified, each associated with a defective PEX gene, all autosomal recessive and all with defective peroxisome biogenesis (Steinberg *et al.*, 2006; Fujiki *et al.*, 2014). As a result of the impaired biogenesis, the major functions, including β -oxidation and plasmalogen synthesis, are defective. All organ systems are affected but the most striking effects are on the nervous system due to abnormal neural migration during prenatal development, with resulting hypotonia, lack of reflexes, seizures, and inability to feed. Milder variants of the syndrome, caused by less consequential mutations in the same set of genes, are called neonatal adrenoleukodystrophy and infantile Refsum disease. Defective individual enzymes of β -oxidation cause similar clinical results. Measurements of decreased enzyme activities and/or metabolite accumulations or deficits form the basis of clinical and prenatal diagnoses. Models of Zellweger syndrome in mice, worms, and fruit flies replicate many features of the human disease, including defects in the nervous system and testis, and are giving valuable insights into the roles of peroxisomes in development (Van Veldhoven and Baes, 2013).

Rhizomelic chondrodysplasia punctata is caused by a defect in one of the peroxisomal enzymes of plasmalogen synthesis or in Pex7, which is required for their import into peroxisomes. Ossification is impaired along with neurological and other abnormalities.

Adrenoleukodystrophy tragically appears in boys in late childhood with cerebral inflammatory demyelination leading to early death. It is caused by defects in the ABCD1 gene that encodes a peroxisomal membrane protein transporter of fatty acids; when defective or missing, oxidative stress occurs, apparently provoked by the accumulation of very long-chain fatty acids. A milder version of this X-linked disorder, adrenomyeloneuropathy, occurs in adults with damage to peripheral and spinal cord neurons. Both forms are seen within the same families, implying the involvement of additional genetic or environmental factors. Bone marrow transplantation was once the only treatment option for the childhood version, but this is now one of the first genetic diseases to be successfully treated by gene therapy. Autologous CD34+ cells received a good copy of the ABCD1 gene via a lentiviral vector and were infused back into patients, resulting in the gradual appearance of ABCD1-positive T and B lymphocytes, monocytes, and presumably microglia cells, implying transduction of hematopoietic stem cells. Clinically, disease progression stopped (Cartier *et al.*, 2009). A second type of therapy, a cocktail of antioxidants, is effective in a mouse model of adrenomyeloneuropathy, preventing axon degeneration and even permitting recovery of lost function. This indicates that oxidative stress is the underlying cause of the neuropathy, and has important implications for other human diseases including Alzheimer's disease and Parkinson's disease, in which oxidative stress likewise occurs (Galea *et al.*, 2012).

A second disease that develops in late childhood is Refsum disease, which is due to a failure in α -oxidation, and begins with deterioration in night vision and a progressive retinitis pigmentosa. It is treated by restricting dietary intake of phytanic acid.

Figure 18 Evolution of the peroxisome. (A) Mammalian peroxisome proteome origins and metabolism, as inferred from proteomics data. The likely evolutionary origins of the proteins: yellow, eukaryotic; green, α proteobacterial; red, actinomycetales; blue, cyanobacterial; and white, undetermined (Gabaldon, 2010). (B) Molecular similarities between (a) the peroxisomal Pex5 import pathway and (b) the ERAD (ER-associated decay) pathway (Schliebs *et al.*, 2010).

Hyperoxaluria type 1 results from the failure of peroxisomal glyoxylate aminotransferase to remove glyoxylate. As a result, it is oxidized to oxalate, and insoluble calcium oxalate is deposited in the kidneys leading to kidney failure and death. This disease can result from mutations that inactivate the enzyme, but in many cases it is due to point mutations that cause a mistargeting of this peroxisomal enzyme to the mitochondria, where it fails to work properly.

Humans deficient in catalase are reported to be more susceptible to diabetes, cancer, and atherosclerosis and perhaps to alterations in aging as well (Fransen *et al.*, 2012).

Conclusion

Peroxisome biology turns out to be far more complex, diverse, and interesting than was imagined at its discovery. Almost 50 years later, we are still discovering new functions, new aspects of its biogenesis, and new pathologies caused by its defects. Some details remain controversial and need further elucidation. Future research is likely to produce more surprises about this fascinating organelle.

Glossary

Glycerolipid The most abundant class of lipids. They are built by esterification of fatty acyl-CoA to the hydroxyl groups of a glycerol molecule. They may also contain ether-linked fatty alcohols.

Lipid Naturally occurring hydrophobic molecules structurally derived from fatty acids or isoprenoids, biosynthetically derived from acetyl-CoA. The major mammalian lipid classes are glycerolipids, sphingolipids, and sterols.

Lipogenesis Cellular de novo synthesis of lipids. This term may be used to describe the de novo synthesis of fatty acyl-CoAs and their further metabolism to glycerolipids, sphingolipids, and sterols.

Lipolysis Term used to describe the degradation of triacylglycerol to glycerol and three fatty acids.

Monotopic membrane protein Proteins that integrate into membranes with a 'hairpin'-like structure. All hydrophilic parts of the proteins face the same side of the membrane.

Neutral lipid Highly hydrophobic lipids without polar/charged groups (phosphate, amine, sugar, or choline). The most common mammalian neutral lipids are triacylglycerol and sterol ester.

Phospholipid Lipids with a phosphate group. Due to the phosphate, they possess a polar, hydrophilic part in addition to the hydrophobic part. Phospholipids are the major components of biological membranes.

Polytopic membrane protein Proteins of which some hydrophilic parts are exposed to one side of the membrane while others face the other side.

Sphingolipid Lipids that differ in structure and biogenesis to the glycerol-based lipids. Their backbone is a long-chain amino alcohol instead of glycerol.

Sterol Hydrophobic polycyclic alcohols that are major components of membranes and precursors of many signaling substances. The most common mammalian sterol is cholesterol.

Basic Structure

Lipid droplets (LDs) are spherical organelles, which appear in the cytosol of some pro- and most eukaryotic cells upon energy surplus. They consist of a core of neutral lipids (NLs) surrounded by a phospholipid monolayer with embedded or loosely associated proteins (Tauchi-Sato *et al.*, 2002). This rather simple structure distinguishes LDs from all other intracellular organelles, which are all separated from the cytosol by membrane bilayers, and hence has some important biological consequences that will be discussed later in this article.

In prokaryotes, the neutral lipid core of LDs frequently contains poly-hydroxyalkanoates like poly-hydroxybutyrate, while storage of triacylglycerol (TAG) or wax esters is relatively rare (Waltermann and Steinbuchel, 2005). In yeasts, plants and animals, TAG is the predominant storage lipid, but other lipids such as sterol esters (SE), retinol esters, free sterols and ether lipids are also stored, often in specialized cell types. Some LDs, particularly in leukocytes, possess internal structures (Melo *et al.*, 2013) with membranes and proteins within the hydrophobic core. For mammalian LDs, the surrounding phospholipid monolayer is mainly composed of phosphatidylcholine (PC, up to 60%), phosphatidylethanolamine (PE, up to 24%), and phosphatidylinositol (PI, up to 8%). Other minor components of the phospholipid monolayer are lyso- and ether-linked forms of PC and PE (Bartz *et al.*, 2007).

The size of LDs ranges from approximately 100 nm in diameter in white adipose cells to the smallest visible LDs of

approximately 100 nm in mammalian cells not preferentially suited for lipid storage. They are usually perfectly round and thereby store a maximum of hydrophobic metabolites within a minimum of membrane layer: Considering the approximate surface area of PC in monolayers ($\sim 1 \text{ nm}^2$ per molecule) and the density of a NL core composed of triolein ($\sim 0.95 \text{ g l}^{-1}$), only 2% PC for small LDs (400 nm in diameter) and 0.5% PC for medium-sized LDs (2 μm in diameter) is needed to shield the hydrophobic core from the aqueous cytosol (Penno *et al.*, 2013).

LD Proteins

Proteome analyses of LDs of different species and cell types (for review see Yang *et al.*, 2012) have shown that LDs contain specific and relatively concise proteomes of about 30–80 different proteins. The unequivocal assignment of LD proteins is complicated due to methodological problems: LDs are isolated using density centrifugations in which the LDs float on top of sucrose gradients while other membranous organelles sink to the bottom fraction. To exclude contaminations of the LD fraction with other membranes, the centrifugation can be repeated several times. Nonetheless, purity is a major concern since large round LDs have relatively little surface compared to the tubular structures of the major contaminant, that is, the endoplasmic reticulum (ER). Hence the purity of an LD preparation may be evaluated by the lack of common ER membrane components such as calnexin. An additional complication, also for the identification of LD proteins via

microscopy, is the fact that LDs are often found partly enwrapped or in very close association with the ER. In some cases it may therefore be hard to discriminate between 'on the LD monolayer' or 'around the LD.' In light microscopy pictures of unfixed cells LD proteins are supposed to show rings rather than egg-cup like structures around the LDs.

Structurally, LD proteins may be divided into four groups:

1. Integral monotopic membrane proteins,
2. Proteins associated with the monolayer by a lipid-anchor,
3. Proteins inserted into the monolayer by an amphipathic helix, and
4. Loosely associated proteins, attached by protein–protein or lipid–protein interactions.

Polytopic integral membrane proteins are sometimes detected in LD proteomes but their presence likely indicates contaminations with closely associated membranes (mostly ER but also mitochondria, Golgi, plasma membrane, and vesicular proteins). This is due to the unique structural organization of LDs in which the hydrophobic core does not provide a luminal aqueous compartment to accommodate polytopic proteins.

Integral monotopic LD proteins (class a) have helix-strand breaking amino acids within a long hydrophobic stretch that provoke a 'hairpin'-like monotopic structure. The 'hairpin' allows for insertion into both, membrane bilayers or a monolayer with a hydrophobic core. This structure, however, is necessary but not sufficient for LD targeting. Additional positively charged amino acids surrounding the hydrophobic stretch seem to be required (Stevanovic and Thiele, 2013). These could directly interact with negative charges of the phospholipid monolayer or could be a sorting signal that selects proteins for transport into the LD monolayer. While integral ER proteins will be able to diffuse into the phospholipid monolayer of nascent LDs, it is less clear how these proteins would shuttle between bilayered membranes and mature cytoplasmic LDs. Constant or transient membrane continuities (hemifusion of the LD monolayer with the cytoplasmic leaflet of other organelles, see Wilfling *et al.*, 2013; Ohsaki *et al.*, 2008) as well as protein-supported transport mechanisms at organelle contact sites are plausible explanations. The protein classes (2)–(4) are at least transiently soluble in the cytoplasm, hence their localization may change more easily between cytosolic and LD-associated (see Figure 1).

The members of the perilipin protein family (see Braasmele, 2007; Bickel *et al.*, 2009) are widespread structural components of LDs and serve as the universal LD protein markers in higher eukaryotes. The five members (Plin1–5) associate with the LD monolayer by amphipathic helices. Some family members are ubiquitously expressed (Plin2–3) while others show tissue-dependent expression profiles (Plin1 and Plin4–5). Plin1–2 are exclusively found on LDs and protect the LD against lipolysis under basal conditions. They are rapidly degraded in the absence of LDs. In contrast to Plin1–2, Plin 3–5 are stable in the absence of LDs and relocate to the surface of LDs depending on the metabolic state of the cell. Plins have lipoprotein-like properties *in vitro*; they may shield lipids from an aqueous environment and hence potentially enable cells to form LD-like structures *de novo* in the cytosol (Bulankina *et al.*, 2009; Bartholomew *et al.*, 2012).

Adipocyte LDs

LDs in adipocytes are especially interesting with regard to widespread health threads such as overweight, obesity, and the metabolic syndrome. Many mammalian species, in particular hibernating animals and also obese humans can accumulate adipose tissue in amounts exceeding any other body tissue. Despite of their obvious importance, very little is actually known about bona fide adipocyte LDs. Currently, most LD research is performed in fibroblasts, hepatocytes, yeast and in differentiated 3T3-L1 cells, a mouse cell line that differentiates into adipocytes-like cells upon treatment with insulin and dexamethasone. 3T3-L1 cells are a major source for adipocytes used in cell biological experiments, and there is no doubt that many aspects of adipocyte biology are well represented by these cells. But it should also be noted that, compared to adipose tissue, 3T3-L1 cells have relatively small, multilocular LDs with a large surface to volume ratio. The reason for the prevalence of 3T3-L1 cells is the problem in handling adipose tissue and freshly isolated adipocytes. Although easily available from liposuction, adipocytes become mechanically extremely sensitive and disintegrate within minutes when separated from the connective tissue, releasing large amounts of fat that float on the surface of the culture system. One interesting aspect of white adipocytes is the mechanism by which they accomplish the transition of multilocular micrometer sized LDs to a single LD that fills the entire cytoplasm leaving only little space for nucleus and other cellular organelles. For a long time, research in this area attempted to find rapid fusion events similar to the SNARE-mediated sub-second time scale fusions of vesicular structures. While results of these attempts have not been convincing (Bostrom *et al.*, 2007; see also Murphy *et al.*, 2010; Ariotti *et al.*, 2012), more recent research has led to the discovery of a slow process of LD coalescence (Nishino *et al.*, 2008). Here, droplets form contact sites followed by slow transfer of material from the smaller to the larger droplet, probably driven by differences in surface tension between differently sized LDs (see Figure 1). At the end of the coalescence event, the smaller droplet has squeezed its entire content into the larger; the fate of its excess surface remains unclear. A specific protein, FSP27, localizes to these contact zones and is essential for the process. Since FSP27 is specifically present in adipocytes, droplet coalescence appears to be the mechanism leading to the formation of large unilocular LDs in adipocytes.

LD Subpopulations

The LD population within a given cell is not homogenous. Simple light microscopy using a lipophilic dye already reveals major differences in size and motility. They may also vary in their metabolic state – while one LD is shrinking due to lipolysis, the neighboring LD may grow because of sustained NL synthesis. It was furthermore suggested that LDs of the same cell differ in their lipid composition with certain droplets storing preferentially TAGs while others store preferentially SEs (Hsieh *et al.*, 2012). However, so far this is not proven and contradicts another report suggesting that SEs may form shell-like structures around TAGs in LDs (Czabany *et al.*, 2008). Without doubt, LDs differ in their protein composition even

Figure 1 Schematic representation of cellular lipid droplets. Lipids droplets originate in the ER due to increased local NL synthesis leading to the formation of a NL aggregation/lens between the two leaflets of the ER (1). Upon further NL synthesis, the NL aggregation is thought to round to a nascent LD that would initially still be attached to the ER via a monolayer continuity, (2) before it would bud off into the cytoplasm. LDs form contact sides with other cellular organelles especially the ER and mitochondria (3) and other LDs (4) where proteins and lipids can be exchanged. LD proteins can diffuse into the LD monolayer via membrane continuities or be transported into the monolayer at organelle contact sites. Transiently soluble proteins are recruited from the cytoplasm and associated with the LD monolayer by lipid-anchors, amphipathic helices or lipid/proteins interactions (5). Apart from the exchange of lipids via membrane continuities or organelle contact sites, different lipids species are likely transported between the LD and other organelles via lipid binding proteins (monomeric transport) (6). LDs possess the enzymatic activities for activation of fatty acids (fatty acyl-CoA ligases (7)), for triacylglycerol synthesis (8), for lipolysis (deesterification of triacylglycerol or sterol ester (9)) and for the remodeling of their phospholipid composition (PLD, PLAs, LPCAT, (10)).

within the same cell. Plin1, for example, associates with large, Plin3 with small and Plin2 with medium sized LDs (Wolins *et al.*, 2006). The presence of one LD protein may even exclude another as it was observed for AUP1 and Rab18. The biological significance for these different subpopulations is an area of active research.

Biogenesis of LDs

The biogenesis of LDs is enigmatic but of high interest. In the prevalent model, LDs originate in the ER upon increased local NL synthesis. As NLs are highly hydrophobic and only soluble up to a few molar percent in phospholipid membranes, the increased local synthesis of NLs leads to an 'oiling out' of NLs between the two leaflets of the ER membrane. By a so far not further identified mechanism, the NL accumulation does not evenly spread within the bilayer but forms a lens-shaped inclusion (see Figure 1) that upon further growth rounds to a

nascent LD that buds off into the cytoplasm. Hence, the nascent LD is surrounded by a phospholipid monolayer originating from the cytosolic leaflet of the ER membrane. This model is based on the fact that the ER is the major site of cellular lipid synthesis and that early nascent LDs are found in close contact to the ER. Moreover, this model nicely explains the experimental findings that the LD monolayer resembles the cytosolic leaflet of the ER (mainly PC and PE, very little sphingolipids) and that integral ER proteins (AUP1, ACSL3, and ALDI) are already found on the first detectable LDs. Recent studies have also described proteins (seipin and FIT1/2) which locate to the assumed LD biogenesis sites of the ER and would regulate the 'oiling out' and budding of the nascent LDs (Szymanski *et al.*, 2007; Gross *et al.*, 2011). However, it was so far not possible to prove this biogenesis model beyond any doubt. This is due to methodological limitations as nascent LDs are thought to be approximately 10 nm in diameter (Zanghellini *et al.*, 2010), a size below the resolution of light microscopy and challenging for currently available electron

microscopy techniques. In addition and in spite of vast screening efforts, so far no single protein has been identified that would be obligatory for LD biogenesis. Only the combined loss of all NL synthesizing enzymes in yeast leads to a loss of LD generation upon fatty acid feeding (Sandager *et al.*, 2002; Oelkers *et al.*, 2002). This is in line with the budding hypothesis that is primarily based on biophysical principles of phase behavior rather than an active protein machinery.

Until new methods arise, which would enable the analysis of 10 nm-sized lipid aggregations, the ER-based budding of LDs explains most if not all experimental findings. Nonetheless other theoretical models may be discussed. LDs could in theory emerge by ‘cutting out’ or vesicular budding from the ER. In addition, they could be formed along the cytoplasmic side of the ER in an egg-cup manner. It is also possible that LDs or some LDs may originate from liposomes *de novo* in the cytoplasm or by fission events of preexisting LDs. It is tempting to speculate that redundant pathways for LD biogenesis exist, resulting in LDs of different origin, protein/lipid composition, and potential internal structure.

Neutral Lipid Synthesis and Lipolysis

The primary function of LDs is the storage of hydrophobic lipids as energy source or biosynthetic precursors. With the exception of free cholesterol in adipocyte LDs, all stored lipids are esters that are synthesized from their components for storage. Stored lipids need to be mobilized upon request, and consequently both NL synthesis and the reverse process of ester cleavage, called lipolysis, are key functions physically connected to LDs.

The classical pathway of TAG synthesis proceeds from glycerol-3-phosphate (G3P) via lysophosphatidic acid (LPA), phosphatidic acid (PA), and diacylglycerol (DAG) to TAG. All of the corresponding enzymatic activities (GPAT, LPAAT, PAP, and DGAT, respectively), as well as the fatty acyl-CoA synthetases, have been attributed to LDs by proteomics or by functional assays (see Figure 1). These assignments include a large range of different species and cell types but no single LD preparation has been shown to produce TAG from G3P and fatty acyl-CoA. Nonetheless, at least the ability to activate fatty acids to the respective CoAs and to synthesize TAG from DAG and fatty acyl-CoA appears to be common to LDs of different species and origin (see Figure 1). In contrast to the synthesis of TAG, LDs are unable to synthesize SEs but need to import them from the ER. LDs can modify their surface PC by exchange of the sn-2 fatty acid, using PLA₂ and LPCAT activities (see Figure 1). Lack of these activities leads to phenotypic alterations in the droplet pool; the physiological significance is unclear. LDs contain numerous sterol synthesizing or modifying enzymes. The presence of these activities on LDs is enigmatic since LDs are neither essential for sterol synthesis nor have been shown to contribute to it. It is tempting to speculate that droplets contain these enzymes in order to separate them physically from their ER-localized substrates to reduce sterol synthesis at high NL load. As a side effect of NL storage, LDs also accumulate other highly hydrophobic substances including xenobiotics and toxic compounds such as polychlorinated biphenyl (PCB) and tetrachlorodibenzodioxin

(TCDD). Sequestration into droplets reduces plasma concentrations of these substances, but adipose tissue itself may become a target for their toxic effects.

All LDs are able to cleave ester lipids to release their constituents (see Figure 1). This process of lipolysis depends on the interplay of its key components ATGL, CGI-58, HSL and, in adipocytes on Plin1. Plin1 localizes to very large droplets and shields the LD from lipolysis under basal conditions. Only upon phosphorylation via PKA, Plin1 releases CGI-58, an activator of the TAG lipase ATGL and recruits the SE and DAG lipase HSL to LDs. There are numerous other accessory proteins and lipases that further stimulate lipolysis and basal LD turnover, which are beyond the scope of this article (please see ‘Further Reading’).

Droplet Dynamics

With the exception of unilocular droplets in adipocytes, LDs are in principle motile organelles that move along microtubules (Spandl *et al.*, 2009). Motility is driven by the motor protein kinesin-1 with typical peak velocities around 1 $\mu\text{m s}^{-1}$, which is much slower than the rapid movement of endocytic vesicles. Such movement was thoroughly studied in syncytial *Drosophila* embryos, where it is part of a generalized cytoplasmic fluid dynamic (Welte, 2009). In other cell types, LD movement contributes to the frequently observed accumulation of LDs in perinuclear regions. These LD accumulations frequently form dense clusters of 10–100 LDs with cell type dependent large variations in cluster frequency and size (see Figure 1). Several LD proteins have been associated with cluster formation, but the physiological function and relevance of LD clustering is unclear (Lohmann *et al.*, 2013).

The size of the cellular LD pools varies not only with nutrient availability, but also during the cell cycle. Detailed studies in yeast have shown that LD breakdown is coordinated with daughter cell formation, mediated by phosphorylation of lipases by cyclin-dependent kinases (Kurat *et al.*, 2009). Much less is known about droplet dynamics in the mammalian cell cycle. During cell division, LDs are evenly distributed between the daughter cells in adipocytes (Nagayama *et al.*, 2007). LDs accumulate upon cell cycle arrest and in apoptotic or necrotic cells, which sometimes makes it difficult to distinguish phenotypes of lipid accumulation from cellular toxicity in screening experiments. Indeed, LD biogenesis is found to be a generalized response upon ER stress (Hapala *et al.*, 2011).

Lipid Droplets and Disease

Many disease conditions are linked to alterations in metabolism with subsequent accumulation or reduction of LDs. A detailed discussion of diseases like obesity and diabetes is beyond the scope of this article (see ‘Further Reading’), but some observations should be mentioned here. Some viruses have connected their life cycle to lipid synthesis and secretion and make use of LDs for their replication. The best-studied examples are the closely related Hepatitis C and Dengue viruses. HCV makes use of various different features of hepatic lipid metabolism (Alvisi *et al.*, 2011). It interferes with lipid

metabolism to increase LD accumulation and induces a structure rich in ER membranes and LDs, called the membranous web. There, several HCV proteins bind to LDs, promoting virus assembly and also virus release.

LDs are also closely related to cancer (Santos and Schulze, 2012). Many cancer types, with the renal clear cell carcinoma as a prominent example, accumulate large amounts of LDs (Straub *et al.*, 2010). This is apparently due to stimulation of growth factor and insulin signaling in cancer cells and supports the cells by supplying energy and protection against oxidative stress. On the other hand, loss of LDs is a hallmark of cancer cachexia, mediated by chronic activation of inflammatory signaling pathways that give rise to an imbalance between TAG synthesis and degradation (Das *et al.*, 2011).

Glossary

Endophylin B1 It is also called Bif-1 and SH3GLB1; suppresses mitochondrial apoptosis; fatty acyl transferase; required for the regulation of mitochondrial outer membrane (MOM) dynamics; acting downstream of Drp1; cytoplasmic localization; targeted to MOM during apoptosis.

GDAP1 Ganglioside-induced differentiation-associated protein 1; mitochondrial fission factor; linked to Charcot-Marie-Tooth (CMT) disease; C-tail anchored MOM protein with two glutathione-S-transferase (GST) domains in the N- and C-terminal regions.

INF2 Inverted formin 2; stimulates both actin polymerization and depolymerization; exists as two isoforms differing in C-terminal sequence: the prenylated ER-bound isoform and nonprenylated cytoplasmic isoform.

MIB Mitofusin (Mfn)-binding protein; inhibits mitochondrial fusion; medium-chain dehydrogenase/reductase family protein.

MITOL/MARCH5 Membrane associated RING-CH E3 ubiquitin ligase; ubiquitin ligase of mitochondrial outer membrane (MOM); with four transmembrane domains (TMDs).

MTP18 Mitochondrial inner membrane (MIM) protein, 18 kDa; stimulates mitochondrial fission.

Prohibitin (PHB1/PHB2) MIM protein; proteins prohibiting cell-cycle progression; form multimeric ring complex in MIM; protein and lipid scaffold; PHB1 are PHB2 50% identical.

Tricoplein/mitostatin (TpMs) Weak homology to trichohyalin, plectin, and myosin; plectin/TpMs genome locus.

Introduction

Mitochondria are double membrane-bound organelles essential for numerous cellular processes, such as aerobic ATP generation, lipid biosynthesis, calcium signaling, and heme and iron-sulfur cluster biogenesis (Chan, 2012; Archer, 2013). Mitochondria are highly dynamic organelles that move along the cytoskeleton, continuously fusing and dividing in healthy cells, and their morphologic changes are essential for maintaining respiratory activity and mitochondrial DNA (mtDNA), and for controlling cellular processes such as embryonic development, cell-cycle progression, immune response, neuronal plasticity, calcium signaling, and apoptotic cell death. Mitochondrial fission contributes to the proper distribution of mitochondria in response to the local demand for ATP, as well as to the elimination of damaged mitochondrial fragments through mitophagy (autophagy for mitochondria) for mitochondrial quality control. Mitochondrial fusion, on the other hand, facilitates the exchange of mtDNA and other components between mitochondria to buffer transient defects in mitochondrial function (Figure 1). Mitochondrial fusion and fission are controlled by four high molecular weight GTPases conserved from yeast to mammals; mitofusins Mfn1 and Mfn2 (Fzo1 in yeast) in mitochondrial outer membrane (MOM) fusion (Figure 2); Opa1 (a causal gene product of optic atrophy type I; Mgm1 in yeast) in mitochondrial inner membrane (MIM) fusion and cristae organization (Figure 3); and cytoplasmic Drp1 (Dnm1 in yeast) in mitochondrial fission (Figure 4) indicating that the fundamental mechanisms controlling mitochondrial dynamics have been maintained during evolution. Abnormal mitochondrial dynamics cause neuronal synaptic loss and cell death in several human neurologic diseases, such as Charcot-Marie-Tooth neuropathy II (CMT2A), Alzheimer's disease, Parkinson's disease, Huntington's disease,

and amyotrophic lateral sclerosis. Furthermore, mitochondrial dynamics are suggested to be responsible for the pathogenesis of other complex diseases, including cancer, cardiovascular disease, and oxidative stress-associated disease, and have also been linked to aging (Chan, 2012; Archer, 2013).

Mitochondrial Fusion Machinery and Regulation

Mfn1 and Mfn2

Mitochondrial fusion of closely apposed mitochondria is a complex regulatory process involving multiple proteins that fuse the MOM and MIM of each mitochondrion, mediating two distinct membrane fusion events. Although fusion reactions between apposing MOMs and subsequent fusion between MIMs are normally highly synchronized, the two processes are functionally separable (Malka *et al.*, 2005). In cultured cells, the lack of mitochondrial fusion leads to defects in oxidative phosphorylation, and because fusion-deficient mitochondria cannot exchange contents, they are unable to restore and maintain the integrity of membranes, mtDNA, and the mtDNA-encoded proteins required for oxidative phosphorylation, and thus become respiration-defective (Chan, 2012).

As mentioned above, three large GTPase proteins, Mfn1, Mfn2, and Opa1 mediate mammalian mitochondrial fusion (Alexander *et al.*, 2000; Delettre *et al.*, 2000; Santel and Fuller, 2001). Mouse knockout (KO) studies clearly demonstrated that Mfn1 and Mfn2 are both essential for mitochondrial fusion (Chen *et al.*, 2003). They are anchored to the MOM through two transmembrane segments (TMs) with both an N-terminal GTPase followed by a coiled-coil heptad repeat (HR1), and a C-terminal HR2 exposing to the cytoplasm, and mediate MOM fusion in a GTPase-dependent manner (Figure 2). Mutations in Mfn2 cause CMT2A (Zuchner *et al.*,

Figure 1 Physiological roles of mitochondrial fusion and fission.

Figure 2 Mfn-mediated mitochondrial fusion and MAM formation. (a) Domain structure of Mfn1/Mfn2. HR1: heptad repeat 1, HR2: heptad repeat 2, TM: transmembrane domain, (b) Mfn proteins in mitochondrial fusion and MAM formation.

2004). The mechanism by which Mfn2 mutations cause CMT2A is not fully elucidated, but there are many loss-of-function Mfn2 mutations found within the GTPase domain in CMT2A. Studies of *in vivo* and *in vitro* membrane fusion

revealed that both Mfn1 and Mfn2 form homo- or hetero-protein complexes that are competent for fusion (Chen *et al.*, 2003; Ishihara *et al.*, 2004). Mfn1-KO results in small fragmented mitochondria that are broadly dispersed within the

Figure 3 Processing of L-Opa1 to S-Opa1 under stable and stress conditions. (a) Domain structure of Opa1 splice variants. MTS: mitochondria-targeting sequence, MPP: mitochondrial processing peptidase, M48: M48-metalloprotease domain, (b) Constitutive and stress-induced processing of L-Opa1.

cell, whereas Mfn2-KO leads to large fragmented mitochondria concentrated near the nucleus (Chen *et al.*, 2003). Mfn1 and Mfn2 are functionally distinct within a hetero-oligomeric complex because the mitochondrial fusion defects associated with CMT2A mutations can be complemented by the expression of Mfn1, but not Mfn2 (Detmer and Chan, 2007). Consistent with these distinct KO phenotypes, purified recombinant Mfn1 exhibits higher GTPase activity than Mfn2 (Ishihara *et al.*, 2004). *In vitro* studies suggest that Mfn1 mediates mitochondrial tethering more efficiently than Mfn2 and thus homotypic *trans* Mfn1 interactions might be responsible for the initial GTP-dependent MOM tethering. How Mfn1 and Mfn2 promote MOM fusion beyond the initial tethering step is unclear. Atlastin (ATL)-mediated endoplasmic reticulum (ER) membrane fusion might represent the mechanistic background. ATL, an ER-bound GTP-dependent membrane fusion protein, is a causal gene product of hereditary spastic paraplegia in humans. GTP binding to ATL induces *trans*-association between the GTPase domains, tethering the membranes together, and GTP hydrolysis induces ATL conformational changes and rotation of the GTPase domain, which pulls the apposing membranes together, leading to membrane fusion (Bian *et al.*, 2011). How MOM and MIM fusion reactions are mechanistically coupled remains unknown.

Modulators of Mitofusin Proteins

In addition to its involvement in mitochondrial fusion, Mfn2 is enriched in the mitochondria-associated membranes

(MAM) of the ER, where Mfn1 and Mfn2 interact on the MOM to form interorganellar bridges (de Brito and Scorrano, 2008). Close contact between mitochondria and the ER is thought to be physiologically important for Ca^{2+} signaling, phospholipid transfer, metabolite exchange, and, therefore, regulation of mitochondrial metabolism and apoptosis (Friedman and Nunnari, 2014). Trichoplein/mitostatin, a keratin-binding protein that partly colocalizes with mitochondria, is involved in the regulation of ER-mitochondria tethering; its expression loosens tethering, whereas knockdown has the opposite effect (Cerqua *et al.*, 2010). Mitochondrial RING-CH E3-ubiquitin ligase, MARCH5/MITOL, regulates tight juxtaposition of mitochondria and ER through MAM by GTP-dependent K63-linked polyubiquitination of the mitochondria-localized form, but not the ER-associated form, of Mfn2 at K192. Therefore, MARCH5/MITOL-knockdown causes MAM dysfunction (Sugiura *et al.*, 2013).

It should be noted, however, that the ER-mitochondria contacts are still formed in mitofusin-deficient cells, however (Cosson *et al.*, 2012), and therefore other proteins may also participate in ER-mitochondria contacts. In yeast, the ER-mitochondria tethering complex, the ERMES complex comprising Mdm34, Mdm10, Mdm12, and Mmm1, forms the contacts involved in phospholipid exchange and mitophagy (Korrmann *et al.*, 2009). In contrast, however, the chemical entities of mammalian MAM, even single or multiple entities with distinct functions, have not been clarified, although many proteins with distinct functions are reported to be localized in MAM, such as PACS-2, Syntaxin17, MAVS, FACL4, PERK,

Figure 4 Mitochondrial recruitment of Drp1 and mitochondrial fission. (a) Domain structure of Drp1 and Drp1 receptors Mff and Mid 51/Mid49. Rab32, and calnexin (Hamasaki *et al.*, 2013; Naon and Scorrano, 2014).

In addition to these players, a 55-kDa mitofusin binding protein (MIB) was identified as a fusion regulator. It is a member of the medium-chain dehydrogenase/reductase protein superfamily and has a conserved coenzyme-binding domain. MIB overexpression in HeLa cells induces mitochondrial fragmentation, whereas MIB silencing leads to the formation of elongated mitochondria and to significant defects in cell growth (Eura *et al.*, 2006). Therefore, MIB functions as a negative regulator of mitofusin proteins essential for cellular function.

Mitochondrial surface-localized phospholipase D (mito-PLD) functions downstream of mitofusin and promotes Mfn1/2-dependent mitochondrial fusion by hydrolysis of cardiolipin to generate phosphatidic acid. The thus-generated phosphatidic acid probably facilitates fusion by generating negative curvature in the opposing lipid bilayers through recruiting or activating other key proteins or through further conversion to other fusogenic lipids (Choi *et al.*, 2006). A recent *in vitro* mitochondrial fusion assay revealed that a Bcl-2 family proapoptotic protein, Bax (soluble monomeric form), specifically stimulates mitochondrial fusion through homotypic Mfn2 *trans* mitochondrial complexes, again indicating functional and mechanistic differences between Mfn1 and Mfn2, although the physiologic significance remains unclear (Hoppins

et al., 2011). Of note, Mfn2 ablation induces ER stress. The Zorzano laboratory recently reported that Mfn2, as an upstream modulator, interacts with an unfolded-response sensor PERK on the ER and coordinately regulates the ER unfolded protein response and mitochondrial function (Schneeberger *et al.*, 2013; Munoz *et al.*, 2013); the mechanism involved in the diet-dependent regulation of metabolism in specific neuronal circuits that affects the metabolic status of animals (see Section Mfn1-, Mfn2-, and Opa1-Dependent Mitochondrial Fusion).

Opa1, a Key Player in MIM Fusion

Opa1 is another key mediator essential for MIM fusion, cristae remodeling, and maintenance of mtDNA (Olichon *et al.*, 2003). Mutations in Opa1 cause autosomal dominant optic atrophy, a degenerative disease of the optic nerve, and Opa1-KO mice are embryonic lethal (E ~13.5) (Alexander *et al.*, 2000; Delettre *et al.*, 2000; Davis *et al.*, 2007). There are eight Opa1 splice variants that are all synthesized as precursor proteins with the mitochondrial localization signal in the N-termini and following hydrophobic stretches, which are responsible for sorting the protein into the MIM (Ishihara *et al.*, 2006). During mitochondrial import, the mitochondrial localization signal of Opa1 precursors is removed by mitochondrial processing peptidase (MPP) to form L-forms

(Ishihara *et al.*, 2006). They are anchored to the MIM as punctate structures exposing both a GTPase domain and a protease cleavable site S1 to the mitochondrial intermembrane space (IMS) (Olichon *et al.*, 2003; Figure 3). In four of the splice variants (variants 4, 6, 7, and 8), exon 5 provides an additional protease cleavage site S2 localized in IMS. The IMS AAA-protease (i-AAA protease) YME1L is responsible for constitutive cleavage of L-Opa1 at S2, whereas constitutive cleavage at the S1 site is mediated by m-AAA proteases (Afg3L1, Afg3L2, and Paraplegin for mice mitochondria, and Afg3L2 and Paraplegin for human mitochondria) and OMA1 (for overlapping activity with m-AAA protease. OMA1 is also involved in the stress-induced L-Opa1 processing; see below). These cleavages yield short isoforms (S-Opa1) that lack the TM segment (Figure 3; Ishihara *et al.*, 2006; Barker *et al.*, 2014). Of note, Chan and colleagues demonstrated using Opa1-KO cells that the L- and S-isoforms have little activity on their own, but the presence of both forms fully complements the function (Song *et al.*, 2007), indicating that mitochondrial function depends on a proper ratio of L- and S-Opa1 isoforms. As detailed below, the mitochondrial stress-induced processing of L-Opa1 by OMA1 occurs only at the S1 site (Song *et al.*, 2007; Baker *et al.*, 2014).

Prohibitins (PHB1 and PHB2), evolutionarily conserved MIM proteins that function as protein- and lipid-scaffolds and are essential for cell proliferation and development, regulate Opa1 processing (Merkwirth *et al.*, 2008). Interestingly, defective phenotypes of PHB1- or PHB2-KO cells, such as those with growth defects, mitochondrial fragmentation, susceptibility to apoptosis, and defective cristae morphogenesis, are all complemented by the exogenous expression of an uncleavable L-Opa1 mutant, indicating that the PHB complex is epistatic to Opa1 processing (Merkwirth *et al.*, 2008). Mutations in the GTPase domain lead to fragmented mitochondria, indicating that GTP hydrolysis is essential for mitochondrial fusion activity. Many Opa1 mutations found in dominant optic atrophy are detected in the GTPase domain. The mitochondrial IMS-exposed region locating next to the GTPase domain is required for the tetramerization and higher-order self-assembly of Opa1 (Ramachandran *et al.*, 2007). In yeast, it was demonstrated that l-Mgm1 functions as a membrane anchor for s-Mgm1 and the GTPase-defective l-Mgm1 mutant is functional (Zick *et al.*, 2009). In this relation, both l- and s-Mgm1 exist as inactive GTPase monomers in the absence of the membrane, but together in *trans* they form a functional dimer in a cardiolipin-dependent manner, providing the building block for higher-order assemblies (DeVay *et al.*, 2009). Cardiolipin is also important for stimulating GTPase and the assembly of Mgm1 and Opa1 (Rujiviphat *et al.*, 2009; Ban *et al.*, 2010).

Several types of mitochondrial dysfunction, such as loss of membrane potential, ATP deficiency, oxidative stress, apoptosis, or loss of mtDNA, induce remarkable fragmentation of mitochondria concomitant with a rapid conversion of L-Opa1 to S-Opa1 isoforms (Ishihara *et al.*, 2006; Chan, 2012). This 'induced' Opa1 processing is mediated by OMA1 (Ehse *et al.*, 2009; Baker *et al.*, 2014). OMA1 is a MIM-bound zinc protease with the N-terminal domain localized at the matrix side of the MIM and the large C-terminal M48 metalloprotease domain exposed to the IMS (Kaesler *et al.*, 2003; Baker *et al.*, 2014) that degrades mis-assembled membrane proteins in yeast

(Figure 3). It is synthesized as a precursor form with the N-terminal MTS. The MIM-integrated mature form of OMA1 is activated by various mitochondrial stimuli to cleave L-Opa1 at the S1 site and, interestingly, this activation is associated with its complete autocatalytic self-degradation. This is considered to be the mechanism ensuring the reversibility of the Opa1-mediated mitochondrial fusion response (Baker *et al.*, 2014; Zhang *et al.*, 2014). Mature OMA1 has an N-terminal domain composed of a hydrophobic region followed by a cluster of positively-charged amino acids; the former stretch is required for OMA1 protease activity, whereas the latter stretch functions as a stress sensor (Baker *et al.*, 2014; Figure 3). Neither knockdown nor overexpression of OMA1 affects mitochondrial morphology in mouse embryonic fibroblast cells, suggesting that OMA1 is dispensable for the balanced formation of L-Opa1 and S-Opa1 by constitutive cleavage under normal conditions. The regulation of Opa1 activities by OMA1 likely affects tissue development or the progression of neurodegenerative diseases. OMA1-KO mice develop and survive normally, although they exhibit marked upregulation of genes in lipid and glucose metabolic pathways, suggesting that the OMA1-Opa1 axis is essential for metabolic homeostasis (Quiros *et al.*, 2012).

Recent genome-wide RNA interference (RNAi) screening led to the identification of ROMO1 (for Reactive Oxygen species Modulator 1), which regulates Opa1-dependent mitochondrial fusion (Norton *et al.*, 2014). It is a 79-amino acid MIM protein that is inserted into the membrane by two TM helices with both N- and C-termini exposed to the IMS, and it promotes mitochondrial reactive oxygen species (ROS) production, cell proliferation, and senescence (Chung *et al.*, 2006; Na *et al.*, 2008). Of note, ROMO1 is also characterized as Higd-1a (for hypoxia-induced gene domain protein-1a), which is required for the morphologic and functional integrity of mitochondria (An *et al.*, 2013). ROM1/Higd-1a binds to Opa1 and stabilizes the Opa1 oligomeric complex and L-isoforms, and maintains the integrity of cristae junction; ROMO1/Higd-1a-depletion results in mitochondrial fragmentation, cristae disorganization, impaired mitochondrial respiration, and increased sensitivity to apoptotic stimuli (Norton *et al.*, 2014). ROMO1/Higd-1a regulates cristae dynamics in response to changes in the mitochondrial redox state and couples mitochondrial ROS to Opa1 oligomerization and cristae junction integrity.
